Indian Institute of Technology, Bombay

Lecture – 32
Basics of SPR: Experimental Design

So, we have been discussing the basics of SPR, surface chemistries and now about the experimental design. In the last lecture we have learnt about various kinds of commercially available surface chemistries to perform different type of bio-molecular interaction studies. Apart from this sensor chip surface there are several other parameters including like impurity, optimum immobilization levels, buffer injection strategies, appropriate reference surface, analyte regeneration which are also involved in aptly designing a surface Plasmon resonance based experiment.

In today's lecture Dr. Srinivas from G. E Healthcare will talk to us and highlight the importance of few of these parameters including sensor surface preparation, immobilization levels, analyte preparation and injection. Experimental design is very crucial for the SPR assay and buffer plays a key role in designing of these experiments. Therefore, Dr. Srinivas will also elaborate on immobilization buffer, regeneration buffer, running buffers and buffer scouting. Some of these are very crucial parameter in the experimental designing of SPR base experiments. So, let us have this lecture by Dr. Srinivas.

(Refer Slide Time: 01:54)

In this session, we will understand how we can develop an assay Biacore or a surface Plasmon assay.

(Refer Slide Time: 02:11)

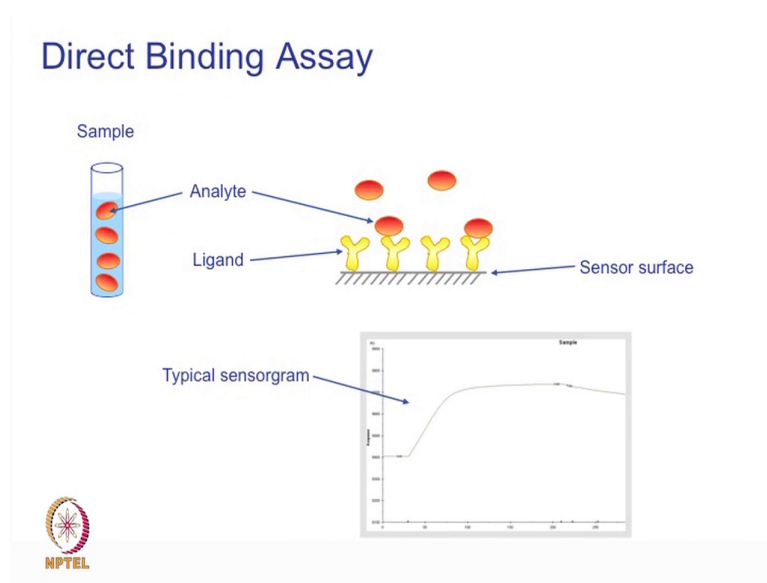

Objectives

- Get the confidence to begin working with your own molecules.
- Learn how to develop and control your assay.
- Know how to immobilize and to evaluate the binding capacity of the ligand.
- Understand how to establish appropriate reference surfaces.
- Learn how to establish regeneration conditions.

And, the objectives of this particular study is how we will understand, how to work with the molecule, how we will develop an assay control an assay we will understand about the reference surfaces, we will also understand about the regeneration of the surfaces and all that.

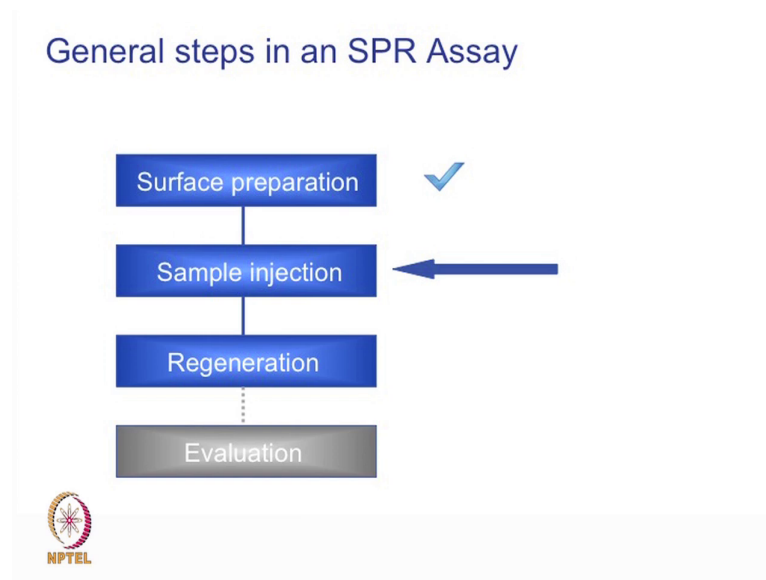

(Refer Slide Time: 02:32)

And, coming to the different varieties of assays that we have one of the very simple way of assay would be a direct binding assay. In a direct binding assay you have the ligand that is immobilized on the sensor chip and an analyte that is present in your or a sample is passed on the surface and the interaction is recorded and so, you can see on the screen the interaction shows this way, a very simple binding and a regeneration.

Whereas, sometimes binding a generally does not go very notice the reason is the responses from the analyte are very very little at that particular stage what we can do is we can pass an enhancement molecule; enhancement binds to the analyte and actually shoots up the responses, so that it can be covered or captured by the system in a prominent way. The way the experiment is designed will actually identify the molecules whether they are binding to one particular side or they are binding to two different sides on the surface of the sensor.

(Refer Slide Time: 03:28)

The various steps that are involved in a Biacore assay are surface preparation, sample injection, regeneration and evaluation. So, we will start with the surface preparation.

(Refer Slide Time: 03:52)

Surface preparation

Immobilization

- What is immobilization?
 - Covalent linking of a ligand or capture molecule to the sensor surface.
- Points to consider
 - What to immobilize?
 - How to immobilize?
 - What immobilization level is appropriate?
 - Which Sensor Chip is suitable?

Surface preparation is nothing, but immobilization and the immobilization generally is by two ways done by two ways – one is a covalent linking and other is a capture method. So, when we actually try to go for an immobilization the very important points that we need to consider are what to immobilize, how to immobilize and what is appropriate level and what is a right sensor chip that is required.

(Refer Slide Time: 04:13)

Surface preparation

What to immobilize?

- Considerations
 - Molecular weight of interactants
 - Tagging of interactants
 - Functional groups
 - Purity
 - Valency (number of binding sites)
 - Binding activity of immobilized interactant must be retained
 - pI
 - Available amount
 - Assay requirements

And, when we are immobilizing we need to know a great amount of information about the protein that we are actually immobilizing or a macromolecule that we are immobilizing. We need to understand the molecular weight of the interactant, the tags that are present on interactant, the functional groups, the pI of the molecule, the purity of the molecule, the available amount and the required assay conditions and the binding activity, valency are some of the important points are which we need to consider when we are going for identifying a ligand.

(Refer Slide Time: 04:34)

Surface preparation

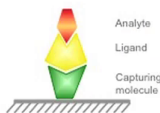

How to immobilize?

- Direct immobilization
 - Covalent chemistry
 - Often heterogenous orientation
 - Higher binding capacity
- Capture approach
 - Orientation-specific
 - Selective capture from crude samples
 - Lower binding capacity

Examples

- Amine coupling
- Ligand thiol coupling
- Surface thiol coupling
- Maleimide coupling
- Aldehyde coupling

Examples

- Streptavidin - Biotin
- Anti-mouse Ig - MAb
- Anti-GST - GST
- NTA - 6His
- Anti-His - 6His
- Anti-FLAG - FLAG

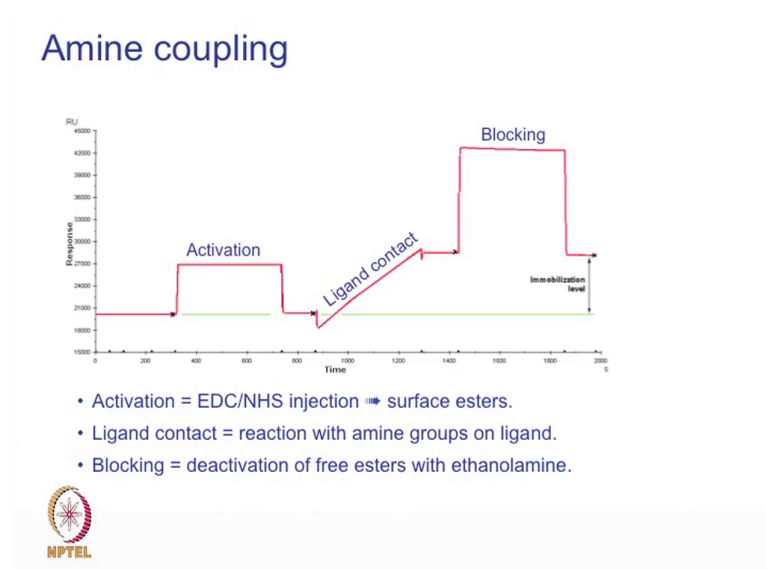

Immobilization is done by direct method as we just discussed and that immobilization can be by covalent chemistry and there will be high binding capacity. And, the ways the very examples of a direct immobilization are amine coupling, thiol coupling, aldehyde coupling, maleimide coupling are the methods that are available.

Whereas, when we look at the capture processes because most of the molecules are explicit these days with tags and when you have tags on the molecule. They are different chips which will capture the tags let us say we have a streptavidin chip that is available and biotin molecules like protein peptides, DNA, RNA all these molecules are actually captured by a streptavidin chip. Most of the time we have anti-mouse, anti-human capture kits are also available and these kits actually will help to capture mouse and human antigens and or anti antibodies and then we will understand the interaction with an antigen.

Also we have the anti-his antibodies which will be able to bind to the his tagged proteins or a NTA chip which will capture histidine molecules and a FLAG molecules are also captured when anti-FLAG antibody and similar way.

The advantage of a capture approach is that capture approaches can be impure or you can have a crude mixture of a ligand when we actually go with a direct binding method or a covalent coupling method. The various covalent coupling methods have been clearly distinguished in the literature. We will take one example here which is an amine coupling which is a very common way of coupling proteins on the sensor surface.

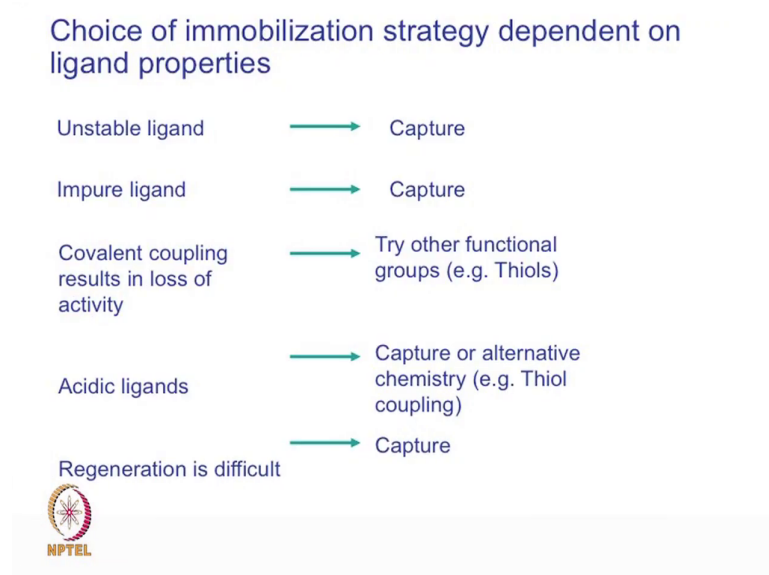

(Refer Slide Time: 06:26)

And, here the activation of the surface is generally done by chemicals EDC and NHS and they will activate the surface esters and the molecules from the amine groups are actually covalent

coupled on the surface of the chip. And, the extra groups that are activated are blocked by ethanol amine.

(Refer Slide Time: 06:54)

The choice of the immobilization strategies generally depend upon the kind of molecule we have let us say we have an unstable ligand then we go for capture. Let us say we have an impure ligand we go for a capture if we have a covalent coupling even do when we do a covalent coupling and that covalent coupling will lead to loss of the activity which means that your analyte is not binding, then we will not proceed for a covalent coupling, but we in that case we will identify a capture process.

Sometimes some of the ligands the pI is very very close to acidic range like 2 or 3 and those kind of molecules we will still prefer to go for a capture process. Sometimes some molecules the regeneration is very difficult, in that case also we go for a capture process. So, this way we

distinguish between what molecules can be captured and what molecules can be covalently coupled. And a very important point during an immobilization design of an immobilization of a molecule or a development of an assay most of the times we need to know the pI or the isoelectric point of a protein.

(Refer Slide Time: 07:56)

The isoelectric point (pI) of the protein

- Defined as the pH at which there is no net charge on the protein

The diagram shows three test tubes illustrating protein charge states at different pH levels relative to the isoelectric point (pI):

- Left tube:** pH < pI, Positive net charge. The protein is shown with a net positive charge, indicated by a higher concentration of positive charges (represented by blue spheres) compared to negative charges (represented by red spheres).
- Middle tube:** pH = pI, No net charge. The protein is shown with an equal number of positive and negative charges, resulting in a net neutral charge.
- Right tube:** pH > pI, Negative net charge. The protein is shown with a net negative charge, indicated by a higher concentration of negative charges (represented by red spheres) compared to positive charges (represented by blue spheres).

The pI isoelectric point is no net charge on the protein and or you can always say that you have equal amount of positive negative charges that are present on the protein. So, for a immobilization strategy it is always better that we go below the pI and at least 1 or 2 units below the pI where the amine groups are perfectly exposed or any of those functional groups are perfectly exposed and will be available for a covalent coupling.

(Refer Slide Time: 08:45)

In this process if we sometimes are not aware of a pI because the molecule is a new molecule and it is just recombinantly expressed and we do not know the molecular isoelectric point in that case we will go for an immobilization pH-scouting in which we will dissolve the protein at different pH and then we tend to pass on the surface of the chip and see what is the responses that are coming up from the molecule.

And, wherever the molecular pH is good enough for the immobilization we go ahead and do immobilization at that particular range. Most of the cases proteins are generally immobilized at 10 millimolar sodium acetate buffer pH 4.5, but this is a general assumption.

(Refer Slide Time: 09:26)

Immobilization levels

- The binding capacity of the surface depends on the immobilization level.
- Different applications require different immobilization levels.
- R_{\max} describes the binding capacity of the surface.

$$R_{\max} = \frac{\text{analyteMW}}{\text{ligandMW}} \times R_L \times S_m$$

R_L = the immobilization level

S_m = the stoichiometric ratio

- The theoretical R_{\max} is often higher than the experimental R_{\max} .

Go for the immobilization level can be done by two ways one is either you go for a controlled immobilization process which is called aim for immobilization. Or you aim for an immobilization level based on the calculated R_{\max} , stoichiometry, binding level and the number of binding sites the molecule has all that is taken into consideration and the level of immobilization is determined.

Once the level of determination is done we will go ahead and ask the machine to immobilize at that particular level. Sometimes we can always go with time and flow mode in which you will just ask the machine to flow your molecule in that particular pH for some amount of time at a particular flow rate and whatever the immobilization happens at the end is the immobilization level.

So, coming to the different steps in our assays the next important step for developing an assay is a sample injection. In a sample injection mode you inject your analyte and the way the molecules are injected depending upon the way the molecular interaction process is happening. If you are screening then there is a very slow way of injecting your molecule slow means the flow rate; when you are injecting kinetics the kinetics are injected with a certain flow rate.

(Refer Slide Time: 10:41)

Different injection options 1(2)

Different injection types give different performance.

| |
|---|
| QUICKINJECT Low sample consumption, greater risk for dispersion of sample and buffer |
| INJECT Moderately low sample consumption, less risk for dispersion |
| KINJECT Best separation of sample from buffer and an undisturbed dissociation, at a cost of higher sample consumption |

So, the sample injection process actually depends upon the flow rate. And, the different modes of injection are generally called as quickinject, kinject and inject and these modes depending upon the mode of interaction or the type of study that you are doing let it be screening, kinetics, thermodynamics, the mode changes and based on the mode the injection process changes and the interaction is recorded at that particular flow and contact time.

(Refer Slide Time: 11:15)

Another important parameter when to be considered when we are designing these experiments is about the bulk. Bulk is nothing, but the difference in the refractive index of running buffer and the sample solution. So, this is a place where most of the people go bad in their assays and will not get a proper a kinetic data. So, I would suggest that people have to equilibrate their analytes to the running buffer, so that to get a good kinetic data.

(Refer Slide Time: 11:42)

Reference surfaces

- If sample matrix and running buffer differ, the bulk contribution can be subtracted by using a reference surface.
- Should be placed upstream of the active surface.

And, another important point in a designing and experiment is the references. There is always a reference upstream your assay, but the references have to be not giving much of a response. Nonspecific response is something that is quite common in these kind of an assay.

(Refer Slide Time: 12:01)

Design of reference surfaces

- Unmodified surface
 - Is acceptable as a reference surface in many cases.
 - To check for non-specific binding to the dextran matrix.
- Activated-deactivated surface
 - Treating the surface with the immobilization procedure, but omitting the ligand.
 - Decreases the negative charge on the surface and may reduce non-specific binding.
- Surface immobilized with dummy ligand
 - A protein that does not bind the analyte may be immobilized to approx. the same level as the ligand to mimic the active surface as closely as possible.

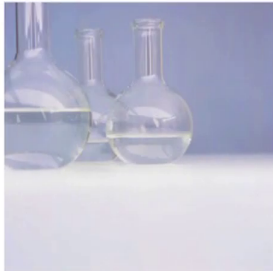

It is the widely followed a different reference surfaces are a non-modified surface in which you take the reference surface as such or a modified surface in which you activate and block the reference surface or a third way of doing is an immobilization of a dummy ligand on the surface of the reference and use it to subtract the non-specific binding. And, coming to the sample or analyte is a major contributor for a bad data. So, it is very important that we purify them or characterize them before our experimentations.

(Refer Slide Time: 12:34)

Sample considerations

- Is the sample homogeneous?
- What is the quality of the analyte?
- Is the analyte active?
- Does the sample aggregate easily?
- Is there non-specific binding?
- Which buffer is most appropriate for my molecules?
- Which injection time should I use?

Homogeneous samples are good enough to be considered please make sure that your samples are highly homogeneous, good quality, active and they do not aggregate and they do not give us a lot of non-specific binding. And, it is very important to understand the right buffer for a right sample and also once we have identified the good sample conditions then we should actually think about the association time and the time at which we need to set up our Biacore experiments.

(Refer Slide Time: 13:14)

Buffer requirements

- Must be 0.2 μm filtered and degassed.
- Most normal assay buffers are compatible with Biacore.
- Include P20 in the running buffer if possible.
- Does my molecule of interest require any specific additives?
- If samples require organic solvents to aid solubility?

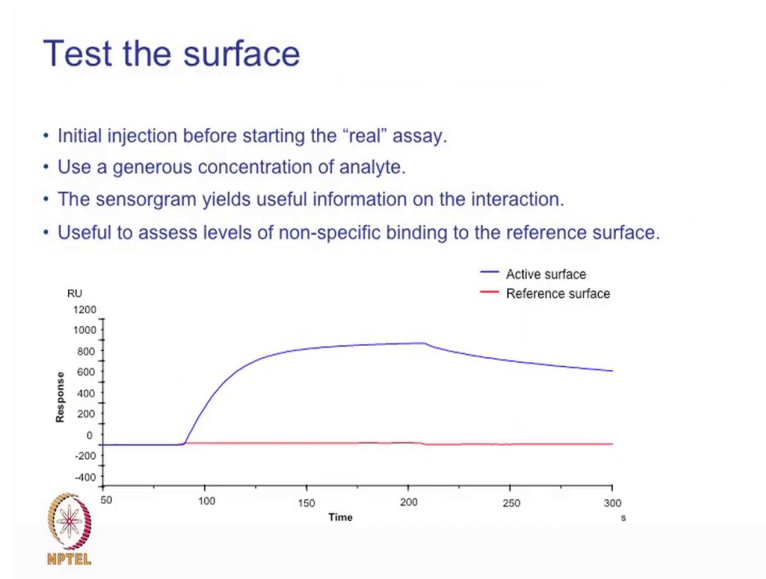

Buffer or a running buffer or a sample buffer or a very important area that we need to understand little bit here. Buffers have to be filtered thoroughly degassed and you know many of the machines have a degasser and a filter that is available in the system, but it is obvious that we can also filter them and degas them prior to experimentation.

All buffers are compatible for SPR systems and it is very important to add sometimes a detergent to make sure that there is a very little amount of non-specific binding most of the molecules or the detergents that are used for into running buffer to prevent non-specific binding is a Polysorbate 20, Tween, SDS all these molecules are added into buffers and buffers are prepared.

And, also sometimes some of the additives are especially required for your running buffer sometimes like metal ions some kind of other activating molecules activators all these need to

be added into your running buffer or a sample buffer to maintain conditions for your experimentation. And, it is very important sometimes when we filter and degas we need to check for the proper filters which are compatible with water and organic solvents. And, once the experimentation conditions are set the analytes are prepared, the ligand is immobilized.

(Refer Slide Time: 14:43)

Then it is a very good way to start by injecting a small amount of your sample to see what is the binding responses that you are getting and to what time you should continue your binding and went to dissociate and all that. That process is called test of a surface you can just test the surface to understand the interaction and also understand the regeneration condition and level of non-specific binding that is coming up from these interactions.

Another part of the assay is regeneration and in regeneration it is very important that we look at what are the different regeneration conditions and what are the ways of doing a

regeneration. Regeneration is nothing, but regenerating the surface back or the immobilized protein and the analyte interaction is being prevented by some kind of a solution so that the surface is regained and again useful for another interaction. So, that process can be studied and they are different ways to study that regeneration conditions, develop the regeneration condition required for a particular interaction.

(Refer Slide Time: 15:49)

Regeneration

- Removes bound analyte completely from the surface.
- The activity of the surface must remain unaffected.
- Efficient regeneration is crucial for high-quality data.

Regeneration as I just said removes the bound analyte completely from the surface. The activity of the surface must remain unaffected after regeneration and an efficient regeneration is crucial for a high quality data. And, regeneration conditions we need to test the regeneration surface, we can do a regeneration scouting before start of an assay or a develop and assay and then identify the right or the appropriate regeneration conditions.

(Refer Slide Time: 16:16)

Choosing regeneration conditions

- Optimal conditions will be specific for the ligand-analyte configuration.
- Suggested alternative starting points for protein ligands:
 - 1. Low pH (10 mM glycine-HCl, from pH 3 to pH 1.5)
 - 2. Ethylene glycol (50%, 75% and 100%)
 - 3. High pH (1-100 mM NaOH)
 - 4. MgCl₂ (1-4 M)

And, some of the very natural or regular usage of regeneration conditions are low pH, ethylene glycol, high pH and magnesium chloride. So, once we identify the proper regeneration solution it is very important for us to identify once we use this regeneration condition are we getting our reference surface on our active surface back after injecting this reference?

In this particular session, we have gone for identifying what is an appropriate ligand or conditions for immobilization of a ligand, what are the different ways we can make an analyte, sample, purify characterize the sample conditions that are required for Biacore assay. And, finally, we went through what is bulk what is nonspecific binding and also we identified or studied about different reference surfaces and also we went through a great detail about regeneration conditions.

(Refer Slide Time: 17:26)

Points to Ponder

- Steps involved in an SPR assay include surface preparation, sample injection, regeneration and evaluation
- The general goal of the immobilization procedure is to attach one of the interacting partners to the sensor surface
- Depending on the application, a known amount of ligand must be immobilized on the sensor chip surface
- The design of the experiment includes the choice of ligand, sensor surface, immobilization chemistry, ligand density and optimum regeneration

NPTEL
MOOC-NPTEL

IIT Bombay

In today's lecture we discussed about the conditions that are required for proper immobilization of the ligand, different methods of analyte preparation and the conditions that are required to perform surface Plasmon resonance space assays. We also talked about the bulk and non-specific binding different reference surfaces and regeneration conditions that could be implemented for the surface stability which is essential for the high quality data.

I would like to reiterate that obtaining some binding information from the SPR experiment is not the only goal. We really want to make sure that you are obtaining very specific binding information and to really achieve that you have to look into many parameters. And, I hope some of the points discussed today, will help you in thinking about the right type of experimental design which is required for you to identify the very specific binding and the

conclusive data from your experiments. We will continue discussing about more of these points in the next lecture.

Thank you.
