### History of Plant Cell and Tissue Culture

- The **concept of cellular totipotency** is inherent in the Cell Theory of Schleiden and Schwann (1838-1839), i.e. cells are autonomous; as, "every cell from a cell".
- Vöchting (1878) succeeded in dissecting plants into smaller and smaller fragments and **keeping the fragments viable and growing**, i.e. to make the plant cells divide and sustain growth.
- G. Haberlandt (1902) introduced **the idea of plant cell and tissue and organ culture**. Reported preliminary findings in, "Experiments on the Culture of Isolated Plant Cells", made a number of **important predictions** in his paper which were **proved half a century later**.
- The development in PCT has been associated to developments in the knowledge base about **nutritional requirements of plant cells, discovery of growth regulators, analytical tools and techniques and development of microscopy**.

History of plant cell cultivation: When cell theory came into picture, parallel discoveries were going on in US and Europe during second world war. The cellular totipotent nature of plant cells was discovered around 1838-39. The idea was to see if the explants can remain viable in the medium for a longer time after taking it out from the plant.

So, the attempts were to keep the fragments which were cut from the parent plant growing and viable. It was necessary to identify what kind of media was needed to sustain that growth. IAA was then discovered. Went was able to find IAA, Indole acetic acid which is an auxin.

Initial discoveries involved the use of complex medium. When coconut milk was used, auxin was discovered. Further it was also discovered that there is a component in coconut milk which is unlike auxin, but is able to support the callus growth. Then in parallel it was also found how to induce callus from single cells. One of the techniques for inducing callus include the nurse tissue technique. A callus of some plant is taken and

a filter paper was placed on top of that callus, and the filter paper was allowed to get wet by the callus.

So, whatever came out of the callus was absorbed by the filter paper. And then on top of that filter paper single cell of a particular plant was placed and it was observed under sterile conditions. And they found that that the single cell started dividing and multiplying, and then callus was found to originate. So, these simple techniques of plant cell and tissue culture formed the basics of plant biotechnology. These were the initial discoveries which were very fast and quick and happened in parallel.

Then it lead on to refined media requirements depending on what kind of culture was required. The initial idea was to just maintain the explant and keep it viable. Then the callus induction was studied. Then somatic embryos also came into light by a simple experiment where carrot discs were put in the suspension. And, then because of agitation some of the single cells got dispersed and came in the medium. Because of the nutrient composition present in the liquid medium, these single cells, rapidly divided and formed embryoid like structures with both primordiums, shoot and the root primordiums later giving rise to the entire plant in the solid medium. This is how regeneration discoveries came into light.

## History of Plant Cell and Tissue Culture

- **First successful culture of excised roots for indefinite periods of time** was achieved by P.R. White (1934) using **indole acetic acid isolated** by the method given by Went (1932)
- In 1939, P. R. Gautheret in Paris, P. Nobecourt in Grenoble, and P. R. White in Princeton, independently succeeded in cultivating cambial tissues of carrot and tobacco for prolonged periods.
- They found that **IAA stimulated the growth of undifferentiated tissue termed callus**, similar to appearance as a wound tissue. It was found that the **callus could be subcultured indefinitely**.
- Gautheret (1939) also discovered **hyper-auxinity in tumor tissues** (auxin non-requiring tissues in culture).
- G. Morel (1952) developed method of **meristem culture for the elimination of viruses for micropropagation**. He discovered the **opines** (octopine and nopaline) of crown gall tissues which **became marker for transformation by Agrobacterium infection**.

Then came *Agrobacterium* mediated transformations where people found that these natural vector systems can cause crown gall disease. When the crown galls were tested,

they found that they have hyper-auxinity. Hyper-auxinity means that they do not require any hormones in the medium to continue their growth. Hyper-auxinity was due to the presence of genes that inherently produced auxins in large amount. The analytical and microscopic techniques were discovered in parallel which helped in the development of plant biotechnology.

Opines were found to be present in these crown galls. Opines act as carbon and nitrogen sources for the bacteria. They are not expressed when present in the bacteria. But, once the bacteria infects the plant cell, the opines get expressed and they start getting produced, which is then utilized by the bacteria as food source. So, initially opine expression is transient.

Opines were used as markers for testing successful transformations. Later more fool proof confirmations such as PCR, was used to check whether T-DNA integration has happened or not.

Then meristem culture came into the picture. So, now, the objective was to see if virus free plants can be obtained which led to the development of meristem culture. Further in the course, the use of meristematic tissues for plant regeneration will be dealt in detail. The reason for the development of meristem culture is because they can lead to production of virus free plants. It is an interesting question to think upon as to why a meristematic region is free of virus and while the other matured parts of the plant are easily invaded by the virus.

## History of Plant Cell and Tissue Culture

- P.R. White (1939) reported for the **first time long term callus culture**, due to incorporation of auxin in the medium. Discovered the **importance of B vitamins** in PCT. The **yeast extract used earlier in the medium was replaced** by three vitamins: pyridoxine, thiamine and nicotinic acid. He formulated the **root culture medium known as White's medium** (1943) later used for various forms of tissue culture.
- F.C. Steward (1948) observed vigorous proliferation of carrot explants due to the **presence of a stimulating substance in coconut milk which was not an auxin**. Discovered **somatic embryogenesis from carrot cells** in suspension after being plated on the solid medium. Miller (1955) **isolated the first cytokinin, Kinetin**.
- J. Reinert (1959) Development of **a complete plant from mature parenchyma**. Discovered bipolar embryo formation when the culture was exposed to a medium lacking high levels of auxins.

Initially complex media were used for *in vitro* plants such as the use of yeast extract which is also used now.. B vitamins were found to be very significant in induction of *in vitro* cultures plant cell and tissue cultures. So, yeast extract was replaced by three of these vitamins, pyridoxine, thiamine and nicotinic acid. So, gradually well-defined media compositions were developed.

Then White's medium came into the picture which was specific to root induction. Then MS media is used for callus induction. Half strength or quarter strength MS compositions also are being widely used which may impact the induction of *in vitro* cultures.

## Totipotency of Plant Cells

- ❑ A graft of a plant can generate a whole new individual out of just a small branch cutting
- ❑ The ability to regenerate normal adult plants from single cells or groups of highly specialized cells
- ❑ Isolated single cells were first successfully grown on a nurse tissue separated by a filter paper and gave rise to a callus tissue (Muir, Hildebrandt, and Riker (1954-1958))
- ❑ Completely isolated single cells (tobacco) were grown in microchambers to form small clumps of cells which then could be differentiated to form adult tobacco plants (Jones, 1960)

Totipotency is the potential of any plant cell to revert back and reprogram itself from a specialized function, and respecialize itself towards a different function.

(Refer Slide Time: 08:18)

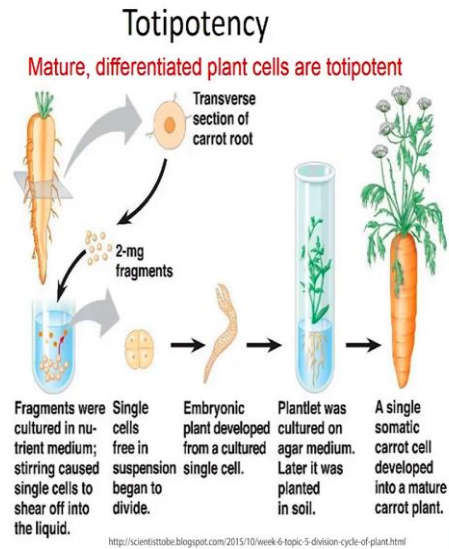

## Totipotency of Plant Cells

- Embryo-like structures or whole plants, or both, were obtained from highly differentiated cells as the pollen grains (gametic and haploid), photosynthetic cells, epidermal cells, and endosperm cells; all of these cell types perform specialized functions.
- In many instances embryoids have been produced *in vitro* from several species of flowering plants which do not show such asexual activity in nature.
- Development of embryoids can be obtained in completely synthetic media from callus tissues as well as in suspension cultures.
- There is a necessity of dissociating tissues into single cells providing a nutritional environment identical to that of the zygote of the embryo sac.

For a totipotent cell to regenerate into a plant, the cell should have embryogenic capacity so as to form primordia for shoot and root generation. And, there has to be a nutrient environment created around the cell to allow it to rapidly divide, similar to a zygote. So, this will lead to regeneration of the cell into a whole plant.

(Refer Slide Time: 08:59)

This slide shows how the entire plant was regenerated from an explant. A disc of carrot was suspended in the liquid. Some of the free cells, by agitation, get dispersed freely in suspension. Totipotent cells with embryogenic competence, start dividing and gets reprogrammed and behave like embryoids, leading to shoot and root primordium. And they are then transferred to the solid medium, giving rise to roots and the entire plant.
