Lecture - 12
Solving Nonlinear Equations

(Refer Slide Time: 00:26)

1D nonlinear equations

- Since the most efficient methods for finding the root of a 1D nonlinear equation work best in a small neighbourhood of the root, it is important to identify an acceptably small interval that bounds the root

- One of the simplest techniques to bound the root of a nonlinear equation is the Method of Bisection

- Suppose the nonlinear function $f(x)$ is continuous in the relatively large interval (a_0, b_0) and $f(a_0) \cdot f(b_0) < 0$ i.e. the root is bounded by (a_0, b_0)

((Refer Time: 00:15)) Series on non linear methods in civil engineering, we are going to focus on solving and methods to Solve Non linear Equations. Last time in our lecture, we briefly introduce this topic. And it said that for non linear equations, typically we use two methods, usually two methods are used to two iterative schemes, two algorithms are generally used for solving the equations.

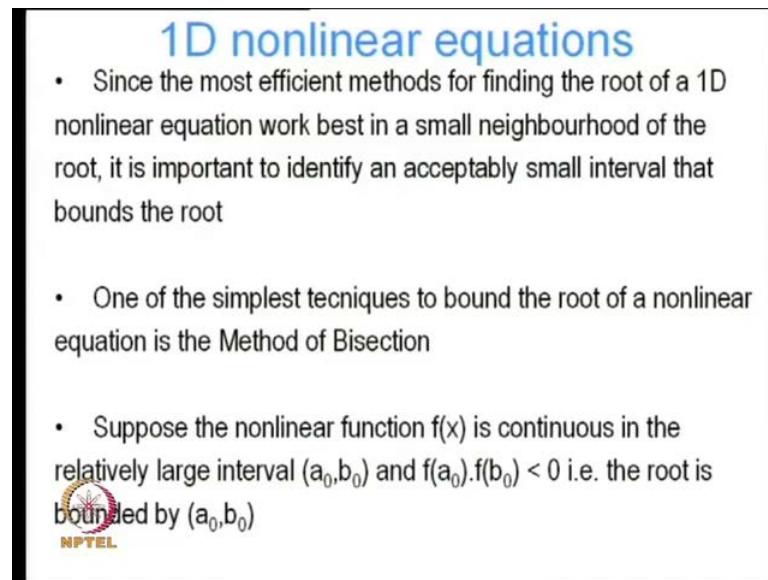

(Refer Slide Time: 00:47)

While, well we looked at this these two pictures right. And we said that any iterative scheme has to bound, we must choose an interval in which to iterate, which bounds the true solution. If we chose an interval which is outside, which does not bound the route right, if you choose an interval like this a, b which does not bound the route. In that case we have no hope of finding a solution.

However, if you choose a very large bound, then it make sense to use a relatively cheaper technique, which is less expensive to narrow down the bound, and then use a more sophisticated technique. Once, the bound has been sufficiently narrowed, the sophisticated techniques are more expensive. So, it make sense to first narrow the bound and then once we have narrowed down the bound sufficiently use a more advanced algorithm, which has got better convergence properties to solve the equation in that narrow bound.

(Refer Slide Time: 01:50)

1D nonlinear equations

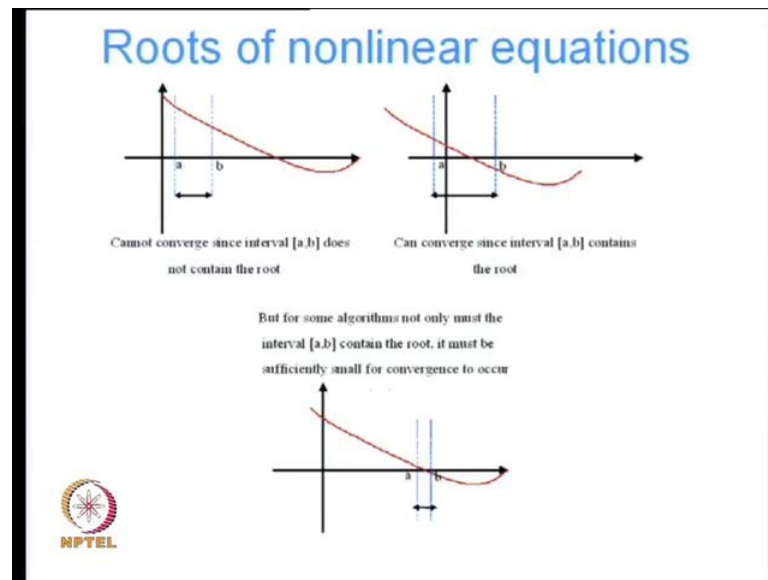

- Since the most efficient methods for finding the root of a 1D nonlinear equation work best in a small neighbourhood of the root, it is important to identify an acceptably small interval that bounds the root
- One of the simplest techniques to bound the root of a nonlinear equation is the Method of Bisection
- Suppose the nonlinear function $f(x)$ is continuous in the relatively large interval (a_0, b_0) and $f(a_0) \cdot f(b_0) < 0$ i.e. the root is bounded by (a_0, b_0)

Since, the most efficient methods for finding the route of a 1D non linear equation work best in a small neighborhood of the root, it is important to identify an acceptably small interval that bounds the root. So, that to make sure that we achieve higher convergence as well as efficient computation, as well as ensure that my computational effect is not too expensive.

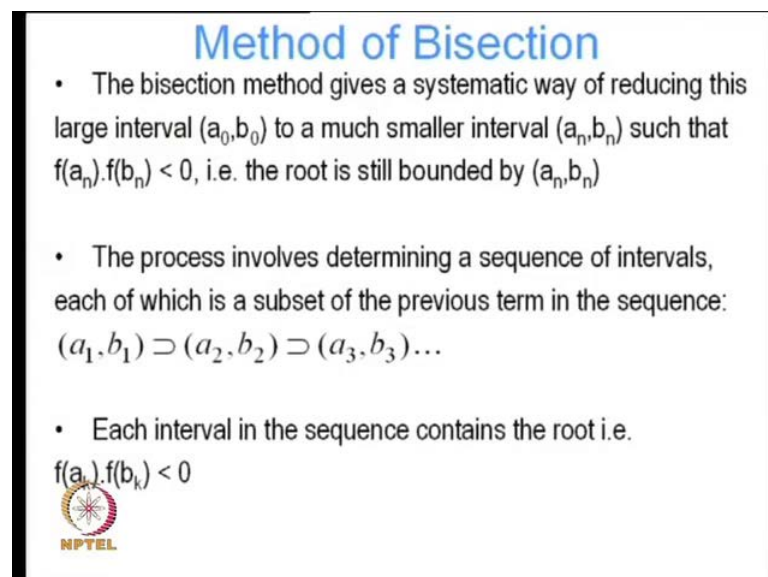

One the simplest methods for bounding the roots of a non linear equation, uses what is known as the bisection method. And let us, suppose that you have a non linear function effects, which is continuous in a relatively large interval a_0, b_0 ; where a_0, b_0 bounds the solution because f of a_0 and f of b_0 have opposite signs. So, product of f a_0 times product of f b_0 is negative; that means, that the root is bounded by a_0, b_0 .

(Refer Slide Time: 02:48)

Basically, what I am saying is that if I look at a_0, b_0 here, then here $f(a_0)$ is positive, here $f(b_0)$ is negative, so $f(a_0), f(b_0)$ is going to be negative.

(Refer Slide Time: 03:06)

The bisection method gives the systematic way of reducing this large interval a_0, b_0 to a much smaller interval a_n, b_n such that $f(a_n), f(b_n)$ is less than 0 that is the root is still bounded by a_n, b_n . So, we started with an interval a_0, b_0 and that, interval bounded the root because sign of $f(a_0)$ was different from the sign of $f(b_0)$, but that interval

was too big. So, you want to find an algorithm like the bisection method to systematically reduce that interval.

So, that my size of the interval becomes small, but at every iteration I want to make sure that my new a_i, b_i the new values of a_i, b_i which are the two bounds of the interval, are actually have opposite signs right they bound the roots. So, $f(a_i)$ dotted with $f(b_i)$ and that will be negative. So, this process involves determining a sequence of intervals, each of which is a subset of the previous term in the sequence, that is a_1, b_1 is greater than a_2, b_2 is greater than a_3, b_3 . So, a_2, b_2 is a subset of a_1, b_1 , a_3, b_3 is a subset of a_2, b_2 and so on and so forth.

So, we systematically make the size of the interval smaller and smaller, but every time we make sure that the interval contains the root, how can I make sure that is true, by making sure that if I evaluate the function values at the two end points, those have opposite signs. So, $f(a_k)$ times $f(b_k)$ is less than 0.

(Refer Slide Time: 04:53)

Method of Bisection

- Let us suppose $f(a_0) < 0, f(b_0) > 0$. The interval $I_k = (a_k, b_k)$, $k = 1, 2, 3, \dots$ is determined as follows:

Given (a_{k-1}, b_{k-1}) , $m_k = \frac{1}{2}(a_{k-1} + b_{k-1})$ where m_k is the mid-point of the interval I_{k-1} . Assume $f(m_k) \neq 0$ since otherwise we have found the root. Compute $f(m_k)$ and take

$$I_k = (a_k, b_k) = \begin{cases} (m_k, b_{k-1}) & \text{if } f(m_k) < 0 \\ (a_{k-1}, m_k) & \text{if } f(m_k) > 0 \end{cases}$$

From construction $f(a_k) < 0, f(b_k) > 0$ and I_k contains a root of $f(x) = 0$

So, let us suppose we start with a very large interval with a_0, b_0 . And let us suppose, that the interval a_0, b_0 bounds the root why because $f(a_0)$ is negative and $f(b_0)$ is positive. The interval I_k which is a_k, b_k , k is equal to 1, 2, 3 or 3 and so on and so forth is determined as follows. So, given a_{k-1} and b_{k-1} , where again $f(a_{k-1})$ is less than 0 and $f(b_{k-1})$ is greater than 0, I find the midpoint of that interval n_k , which is half of $a_{k-1} + b_{k-1}$.

And then assuming that $f(m_k)$ is not equal to 0 because after all if $f(m_k)$ is equal to 0; that means, I have already found the root, but suppose that $f(m_k)$ is not equal to 0, then I look at the sign of f at m_k . And then check whether $f(m_k)$ is positive or $f(m_k)$ is negative. So, if $f(m_k)$ is negative in that case, my new interval is going to be m_k, b_{k-1} why because I knew that $f(b_{k-1})$ is positive right. So, if $f(m_k)$ is negative; that means, m_k and b_{k-1} the root must lie between m_k and b_{k-1} right.

Similarly, if $f(m_k)$ is positive I know that since $f(a_{k-1})$ is negative; that means, the root must lie between a_{k-1} and m_k right. So, depending on the sign of $f(m_k)$ I choose my new interval, which is going to be a_k, b_k it is going to be m_k, b_{k-1} or a_{k-1}, m_k . So, from construction $f(a_k) < 0$, $f(b_k) > 0$ because this is how I constructed my interval.

So, $f(a_k) < 0$, $f(b_k) > 0$ and I_k is always going to contain a root of $f(x) = 0$. So, every time I make I half it, basically that is why it is called the method of bisection, so initial interval, next iteration that size becomes half, next iteration becomes 1 fourth, 1 eighth. So, every time it becomes half, so that is why it is known as the method of bisections.

(Refer Slide Time: 07:19)

Method of Bisection

- After k steps, we have contained the root in the interval (a_n, b_n) of length: $(b_n, a_n) = \frac{1}{2}(b_{n-1}, a_{n-1}) = \dots = \frac{1}{2^n}(b_0, a_0)$
- Thus at each step the size of the interval is reduced by half.
- When the interval is sufficiently small, we can take m_{n+1} as an estimate of the root α i.e.

$$\alpha = m_{n+1} \pm d_n. \text{ The error } d_n = \frac{1}{2^{n-1}}(b_0 - a_0)$$
- The method will eventually converge to the root with an acceptable accuracy so long as n is large. However convergence is very slow.

After k steps, we have contained the root in the interval a_n, b_n . So, now my root after n steps, basically it should be n steps really. After n steps I had contained the root in the interval a_n, b_n and the length of b_n, a_n is half of b_{n-1}, a_{n-1} , b_{n-1}, a_{n-1}

a_{n-1} is again half of b_{n-2} , a_{n-2} and so on and so forth. Until I can write b_n , a_n is equal to $\frac{1}{2}$ to the power n $b_0 - a_0$ thus at each step the size of interval is reduced by half.

So, if I take sufficiently large number of steps, so 2 to the power n the size of the interval is going to become, very small. And that interval is be going to contain the root right, then the size of the interval is very small is sufficiently small, we calculate the midpoint of the interval m_{n+1} . Suppose, my a_n, b_n interval has reached the sufficient size restriction right, that my interval is now sufficiently small. Then I say that my root, my root is actually at the midpoint of the interval.

And error in the root is given by plus minus d_n , where the error in the root is d_n is equal to $\frac{1}{2^{n-1}} (b_0 - a_0)$. So, I know the root up to this, up to the accuracy given by d_n right and suppose, if my interval size, if I have sufficiently large intervals then since d_n goes as $\frac{1}{2^{n-1}}$ say suppose, I have like 16 bisections right $\frac{1}{2}$ to the power 16 minus 1 that is a very small number right. So, my d_n my error is going to be sufficiently small and I can say that m_{n+1} is my root up to this accuracy.

So, the method will eventually converge to the root with an acceptable accuracy. So, long as n is large, so what is the good thing about this method, good thing about this method is that, it is always going to converge right. If, I take sufficiently large number of n 's it is always going to converge; however, the convergence is relatively slow, compared to some of the other methods that we are going to look at right.

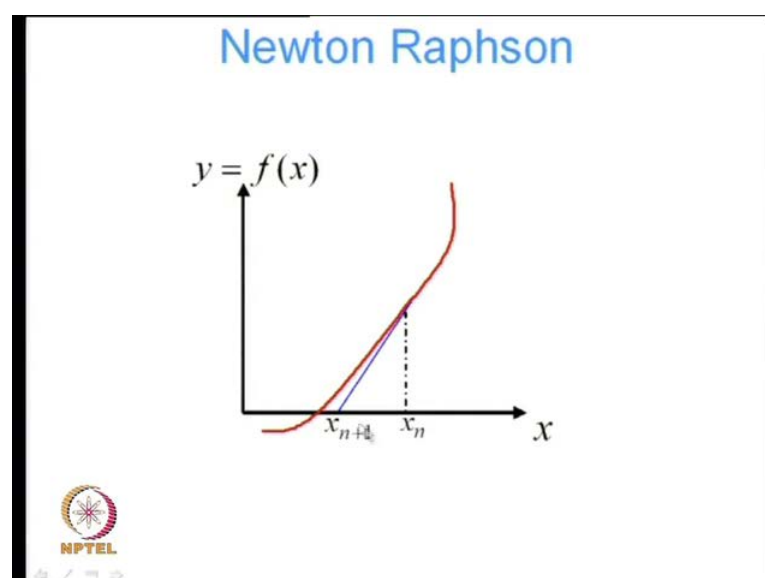

(Refer Slide Time: 09:45)

Newton Raphson

- The Newton Raphson method is defined by the following iteration rule:
$$x_{n+1} = x_n + h_n, \quad h_n = -\frac{f(x_n)}{f'(x_n)}$$
- The function $f(x)$ is approximated by its tangent at the point $(x_n, f(x_n))$ and x_{n+1} is taken as the abscissa of the point where the tangent intersects the x axis
- The iteration is stopped when $|h_n|$ becomes less than the error one is willing to accept in the root
-  The convergence properties of the method determine the rate at which the criterion is achieved

One such method, we are going to look at is the Newton raphson method which is defined by the following iteration rule, where the iteration rule says, that at a new increment at a new iteration I calculate my $x_n + 1$ using my old value x_n plus an update which is given by h_n . And what is the update, that update is given by the quotient of the function evaluated at x_n and its derivative evaluated at x_n taken with a negative sign. Why do we have this update formula, well basically it is because the function $f(x)$ is approximated by its tangent at the point $x_n, f(x_n)$ and $x_n + 1$ is taken as the abscissa of the point, where the tangent intersects the x axis.

(Refer Slide Time: 10:38)

Basically, if you look at this picture given x_n , we say that I am going to do a linearization of my function. So, my function is non linear, I am going to assume that within the small range it behaves like a linear function right. And what is that linear function going to be that linear function is going to pass through $x_n, f(x_n)$ and it is going to have a slope which is equal to this slope at x_n right.

So, this is my straight line, blue line is my straight line which approximates my non linear function which is given by the red line. And what is the criteria, that it passes through this point $x_n, f(x_n)$ right it satisfies the function value at x_n and its slope is given by the slope of the function at x_n right. And the point at which it intersects the x axis that is going to be my new update, my new iteration value x_{n+1} .

(Refer Slide Time: 11:41)

Newton Raphson

- The Newton Raphson method is defined by the following iteration rule:

$$x_{n+1} = x_n + h_n, \quad h_n = -\frac{f(x_n)}{f'(x_n)}$$
- The function $f(x)$ is approximated by its tangent at the point $(x_n, f(x_n))$ and x_{n+1} is taken as the abscissa of the point where the tangent intersects the x axis
- The iteration is stopped when $|h_n|$ becomes less than the error one is willing to accept in the root
-  The convergence properties of the method determine the rate at which the criterion is achieved

So, x_{n+1} is equal to x_n minus $f(x_n)$ by $f'(x_n)$. The iteration when we stopped the iteration, well when we stop the iteration then my update becomes smaller and error that I will willing to accept in the root right. So, if I find that my changes, my solution, my update from iteration to iteration, my solution change is, so small that it is negligibly small, then I say that I have converged right and that is my solution. The convergence properties of the method determine the rate at which the criterion is achieved.

So, we said that, the bisection method well it is always going to converge that works bad about it is that it converges very slowly right. So, that is why we went for this method

Newton Raphson and we say therefore, Newton Raphson method, the convergence properties are comparatively better right. And we shall see why the convergence properties of Newton Raphson method are better.

(Refer Slide Time: 12:43)

Convergence of iterative methods

Convergence of an iterative method that generates a sequence $x_0, x_1, x_2, \dots, x_n$ is defined in the following manner:

Let $\{x_n\}$ be a sequence that converges to α and set $\epsilon_n = x_n - \alpha$.

If there exists a number p and a constant $C \neq 0$ such that

$$\lim_{n \rightarrow \infty} \frac{|\epsilon_{n+1}|}{|\epsilon_n|^p} = C$$

then p is called the order of convergence of the sequence and C the asymptotic error constant. For $p = 1, 2, 3$ the convergence is said to be linear, quadratic, cubic etc.

So, convergence of an iterative method that generates a sequence is defined in the following manner. So, this is stated it in a somewhat formal way, so let us suppose x_n be a sequence. So, that x_n, x_0, x_1, x_2, x_3 , so these are my iterates right in my iterative method and this is a sequence, that converges to the true solution alpha. So, that as n goes to infinity x_n is going to tend to alpha right.

And let me set epsilon n is equal to x_n minus alpha. So, I want to define the error, at any iteration n and how am I going to define that I am going to define that by, saying epsilon n is equal to x_n minus alpha. So, whatever is my iterate value, I subtract the true solution from that that gives me the error epsilon n . Now, if there exist a number P and a constant C which is strictly not equal to 0.

Such that, limit of mod of epsilon n plus 1 by mod of epsilon n to the power P when n tends to infinity is equal to the constant C . Then we say that my iterative method has ordered of convergence equal to P and C is my asymptotic error constant. So, when I have very large, so what in words what does this mean, it means that when I increase the number of iterations right, when if I sufficiently Largent n , if I look at iteration n and I if I look at the iteration n and I look at iteration n plus 1.

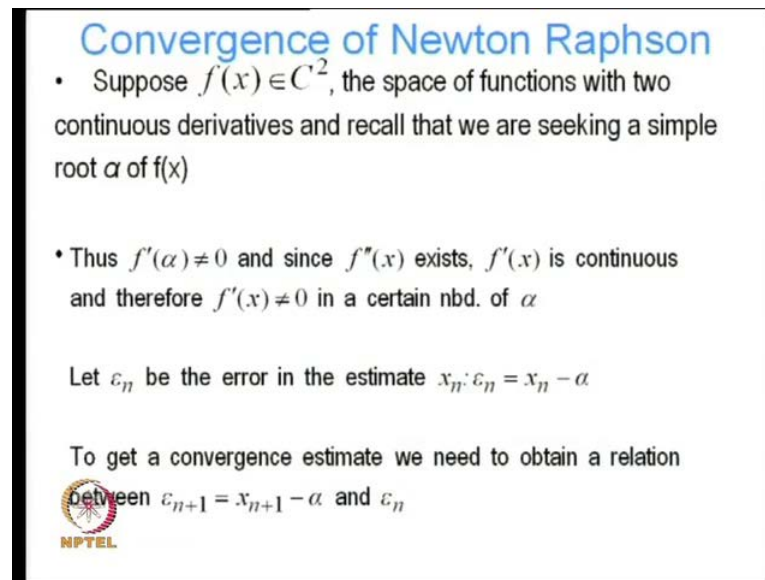

I calculate the error at iteration n , how do I calculate error iteration n , by taking the value of the iterate minus the true solution. And taking the normal of that how do I calculate the error iteration n plus 1, I again calculate the value of the iterate minus the true solution $x_{n+1} - \alpha$ right. So, that gives me my ϵ_{n+1} and ϵ_n and if it turns out that ϵ_{n+1} is equal to some constant, times ϵ_n to the power P then I say P is called the order of convergence. So, let us think about it like this in just using numbers see suppose, at iteration n I have an error ϵ_n is equal to 0.1 right.

And then at iteration $n+1$ I have an error which is 0.01. So, in that case what is going to be my P and what is going to be my c it is obvious that P is going to be 2 and c is going to be 0.1 because $0.1^2 = 0.01$ is my error at $n+1$, so 0.01 is equal to 0.1^2 , so the error has been reduced by squared the magnitude of the previous error. So, it is converged it has got quadratic convergence right, so P is equal to 2.

So, it has got quadratic convergence, which is very good actually and for P is equal to 1, 2 we can P can be anything P can be 1, 2 or 3 convergence is said to be linear quadratic, so for the bisection method, we have typically linear convergence P is equal to 1 for the Newton Raphson method, we have P is equal to 2. But, this P is equal to 2 we get quadratic convergence only near the root right, when it sufficiently close to the root we get quadratic convergence.

We will look at the secant method and secant method is somewhere between linear and quadratic, it is 1.6 something right. So, the order of convergence is better than my bisection method, but worse than my Newton Raphson method right. So, the larger the value of P , the better is my better are the convergence characteristics of my algorithm; that means, if I start with an error 0.1, if I have convergence, If I have quadratic convergence then it is going to go to 0.1 times, 0.1 forth root of that right. So, that is going to 10 to the power minus 5. So, 1 iteration it was 10 to error was 10 to the power minus 1, the next iteration it is going to be 10 to the power minus 5. So, that is wonderful right, so I need to take fewer iterations, when my error is going to converge my solution is going to converge faster.

(Refer Slide Time: 17:29)

Convergence of Newton Raphson

- Suppose $f(x) \in C^2$, the space of functions with two continuous derivatives and recall that we are seeking a simple root α of $f(x)$
- Thus $f'(\alpha) \neq 0$ and since $f''(x)$ exists, $f'(x)$ is continuous and therefore $f'(x) \neq 0$ in a certain nbd. of α

Let ϵ_n be the error in the estimate x_n : $\epsilon_n = x_n - \alpha$

To get a convergence estimate we need to obtain a relation between $\epsilon_{n+1} = x_{n+1} - \alpha$ and ϵ_n

So, let us suppose, f of x the function f of x belongs to the class of functions C^2 which is basically a mathematical nomenclature, for saying that this function belongs the class of functions, which have continuous second derivatives right. C^0 means, only the function is continuous and it is partial, it is derivatives are piecewise continuous, C^1 means that function is continuous, as well as the derivative C^2 means the function is continuous as well as it is second derivative right.

So, suppose f of x belongs to C^2 the space of functions, with two continuous derivatives and let us, we call that we are seeking a simple root α of f x . Last class we talked about simple roots and multiple roots, let me try to or we will we are going to talk about that later again. So, since it is a simple root, I know that f' prime of α is not equal to 0 right and since, this is the definition of a simple root right, a simple root says that at the root where, the function f of α is equal to 0, f' prime of α is not equal to 0 that is it is not a stationary point right.

The function is going like this or like this, it is not a stationary point at the root right. So, it because at α what does f' prime α equal to 0 means; that means, there are multiple roots right. So, f' prime α not equal to 0 means, that there are that is a simple root right it is just crossing like that, right and since, we said that f of x belongs to C^2 to the space of functions with, continuous second derivatives; that means, f'' double prime of x must exist, right since if something is continuous it had better exist right.

Since, the second derivative is continuous $f''(x)$ must exist, right and $f'(x)$ is continuous, why is $f'(x)$ continuous well. So, if $f'(x)$ is not continuous, there is no chance of $f''(x)$ being continuous, so $f'(x)$ must be continuous. And therefore, $f'(x)$ is not equal to 0 in a certain neighborhood of α , why because $f'(\alpha)$ is not equal to 0 and I know that, $f'(x)$ is continuous.

Therefore, that what is continuous means, there is a non 0 δ I can draw always a non 0 sphere, around α where $f'(x)$ is not equal to 0 right. Because, $f'(\alpha)$ is not equal to 0 right, at α $f'(\alpha)$ is not equal to 0 and I know that $f'(x)$ is continuous; that means, there is a non 0 interval, centered around α at which $f'(x)$ is not equal to 0 right I may. So, there is there must exist a neighborhood, centered around α in which $f'(x)$ is not equal to 0.

So, let ϵ_n be the error in the estimate x_n . So, ϵ_n is equal to $x_n - \alpha$, so that is the error at iteration n , is $x_n - \alpha$, to get a convergence estimate we need to obtain a relation, between ϵ_{n+1} and ϵ_n . So, what is ϵ_{n+1} , it is $x_{n+1} - \alpha$.

(Refer Slide Time: 21:08)

Convergence of iterative methods

Convergence of an iterative method that generates a sequence $x_0, x_1, x_2, \dots, x_n$ is defined in the following manner:

Let $\{x_n\}$ be a sequence that converges to α and set $\epsilon_n = x_n - \alpha$.

If there exists a number p and a constant $C \neq 0$ such that

$$\lim_{n \rightarrow \infty} \frac{|\epsilon_{n+1}|}{|\epsilon_n|^p} = C$$

then p is called the order of convergence of the sequence and C the asymptotic error constant. For $p = 1, 2, 3$ the convergence is said to be linear, quadratic, cubic etc.

So, we saw what did, we see that this is how we obtain a convergence estimate right, by obtaining a relationship between the error at the $n+1$ 'th iteration and the error at the

n'th iteration. If we can write a relation between epsilon n plus 1 and epsilon n, I can find out what is my rate of convergence right.

(Refer Slide Time: 21:30)

Convergence of Newton Raphson

- Suppose $f(x) \in C^2$, the space of functions with two continuous derivatives and recall that we are seeking a simple root α of $f(x)$
- Thus $f'(\alpha) \neq 0$ and since $f''(x)$ exists, $f'(x)$ is continuous and therefore $f'(x) \neq 0$ in a certain nbd. of α

Let ϵ_n be the error in the estimate x_n : $\epsilon_n = x_n - \alpha$

To get a convergence estimate we need to obtain a relation between $\epsilon_{n+1} = x_{n+1} - \alpha$ and ϵ_n

So, to get a convergence estimate we need to obtain a relation between, epsilon n which is equal to x n plus 1 minus alpha and epsilon n.

(Refer Slide Time: 21:39)

Convergence of Newton Raphson

Expanding $f(x)$ in a Taylor series about α :

$$f(\alpha) = f(x_n) + (\alpha - x_n)f'(x_n) + \frac{1}{2}(\alpha - x_n)^2 f''(\xi), \xi \in [x_n, \alpha]$$

Dividing by $f'(x_n)$ which is not equal to zero in a nbd of α :

$$\frac{f(x_n)}{f'(x_n)} + (\alpha - x_n) = \alpha - \left[x_n - \frac{f(x_n)}{f'(x_n)} \right] = \alpha - x_{n+1} = -\frac{(\alpha - x_n)^2 f''(\xi)}{2f'(x_n)}$$

$$\therefore \epsilon_{n+1} = \frac{1}{2} \epsilon_n^2 \frac{f''(\xi)}{f'(x_n)} \quad \text{As } x_n \rightarrow \alpha, \quad \frac{\epsilon_{n+1}}{\epsilon_n^2} \rightarrow \frac{1}{2} \frac{f''(\xi)}{f'(\alpha)}$$

- Since $\epsilon_{n+1} \propto \epsilon_n^2$ the Newton-Raphson method is said to be quadratically convergent

So, expanding f of x in a Taylor series about alpha, so what we do, we will expand it f of x in a Taylor series about alpha, so we get. So, basically we are writing it as f of x n plus alpha minus x n plus, so this is my perturbation alpha minus x n, so f of x n plus alpha

minus x_n plus f' of x_n plus I am putting this as a remainder term, right like a Taylor series expansion this is the remainder, provided that x_i belongs to the interval x_n and α right.

So, basically I just do a Taylor series expansion of f about α . Then I divide throughout by f' of x_n and how can I divide because I know that f' of x_n is non 0 in a neighborhood of α , if it I cannot divide anything by 0 right. So, because I am assured that f' of x_n is non 0 in a neighborhood of α , so I can divide it by f' of x_n . So, I get f of x_n plus x_n prime of x_n plus α minus x_n and this f' of x_n goes away, so this I can rewrite as α minus x_n minus f of x_n by f' of x_n just by rearranging terms right.

So, I am just pulling this within the bracket and putting the x_n here and bring out α there right, this with this, what is this, this is exactly my expression for x_{n+1} right it is the iterate at $n+1$. So, this is my expression for the new iterate, so this becomes α minus x_n plus 1 and this is equal to this term, right this is equal to this term which is equal to α minus x_n square f'' of ξ and I have divided throughout by f' of x_n . So, f' of x_n appears at the bottom right.

So, what do we have, so that not, but what is this α minus x_n plus 1 is just ϵ_{n+1} right, this is the error at the $n+1$ 'th iterate, this α minus x_n is nothing, but ϵ_n right. So, I can write ϵ_{n+1} is equal to half ϵ_n square f'' of ξ divided by f' of x_n right, and as x_n tends to α f' of x_n is going to tend to f' of α . So, I can write ϵ_{n+1} divided by ϵ_n square tends to half f'' of ξ by f' of α this is a constant right, because I am evaluating it at ξ and α . So, again I have got this error estimate this ratio of these errors, I have got it in that form.

(Refer Slide Time: 24:33)

Convergence of iterative methods

Convergence of an iterative method that generates a sequence $x_0, x_1, x_2, \dots, x_n$ is defined in the following manner:

Let $\{x_n\}$ be a sequence that converges to α and set $\epsilon_n = x_n - \alpha$.

If there exists a number p and a constant $C \neq 0$ such that

$$\lim_{n \rightarrow \infty} \frac{|\epsilon_{n+1}|}{|\epsilon_n|^p} = C$$

then p is called the order of convergence of the sequence and C the asymptotic error constant. For $p=1,2,3$ the convergence is said to be linear, quadratic, cubic etc.

Epsilon n by 1 plus epsilon n to the power P is equal to C I can clearly identify.

(Refer Slide Time: 24:41)

Convergence of Newton Raphson

Expanding $f(x)$ in a Taylor series about α :

$$f(\alpha) = f(x_n) + (\alpha - x_n)f'(x_n) + \frac{1}{2}(\alpha - x_n)^2 f''(\xi), \quad \xi \in [x_n, \alpha]$$

Dividing by $f'(x_n)$ which is not equal to zero in a nbd of α :

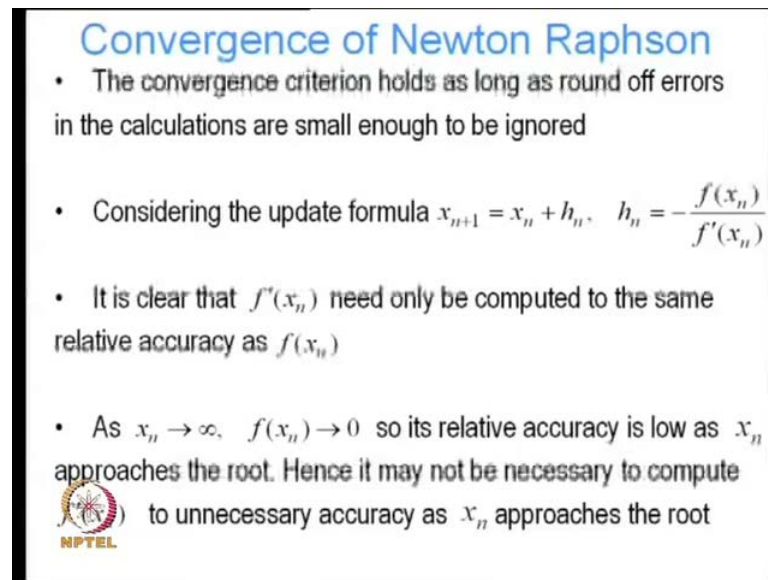

$$\frac{f(x_n)}{f'(x_n)} + (\alpha - x_n) = \alpha - \left[x_n - \frac{f(x_n)}{f'(x_n)} \right] = \alpha - x_{n+1} = -\frac{(\alpha - x_n)^2 f''(\xi)}{2f'(x_n)}$$
$$\therefore \epsilon_{n+1} = \frac{1}{2} \epsilon_n^2 \frac{f''(\xi)}{f'(x_n)} \quad \text{As } x_n \rightarrow \alpha, \quad \frac{\epsilon_{n+1}}{\epsilon_n^2} \rightarrow \frac{1}{2} \frac{f''(\xi)}{f'(\alpha)}$$

- Since $\epsilon_{n+1} \propto \epsilon_n^2$ the Newton-Raphson method is said to be quadratically convergent

That in that case P, is in this case P is equal to 2 and my constant C is given by this. So, since epsilon n plus 1 goes as epsilon n square, the Newton Raphson method is said to be quadratic ally convergent.

(Refer Slide Time: 25:00)

Convergence of Newton Raphson

- The convergence criterion holds as long as round off errors in the calculations are small enough to be ignored
- Considering the update formula $x_{n+1} = x_n + h_n$, $h_n = -\frac{f(x_n)}{f'(x_n)}$
- It is clear that $f'(x_n)$ need only be computed to the same relative accuracy as $f(x_n)$
- As $x_n \rightarrow \alpha$, $f(x_n) \rightarrow 0$ so its relative accuracy is low as x_n approaches the root. Hence it may not be necessary to compute $f'(x_n)$ to unnecessary accuracy as x_n approaches the root

 NPTEL

So, the convergence criterion holds as long as round off errors. So, what are the criteria, first criteria is that we have assumed everywhere that, we are close to the root right, we have assumed that in a neighborhood, we have looked at a neighborhood where, f' of x_n is not equal to 0. So, we have to stay within sufficiently close to the root, right because far away from x , far away from the root I have no guarantee that f' of x_n is equal to going to be non 0 right.

Because, f' of α is not equal to 0, I know that if I look at a sufficiently close interval centered around the root, I can always be sharpened at f' of x_n is not going to be 0. But, if I move away from that from α and there is no guarantee, f' of x_n may be, may not be equal to even may be equal to 0 right may not be non 0. So, when that whole proof is going to break down, right my whole proof of convergence is going to break down.

So, you can see why it is very important to keep in mind, that the Newton raphson method convergences quadratic ally near at the root right. So, that assumption is built in there, far away from the root there is no guarantee that it is going to converge linearly right. The other assumption that, we made is that round off errors in the calculations are small enough to be ignored right.

(Refer Slide Time: 26:29)

Convergence of Newton Raphson

Expanding $f(x)$ in a Taylor series about α :

$$f(\alpha) = f(x_n) + (\alpha - x_n)f'(x_n) + \frac{1}{2}(\alpha - x_n)^2 f''(\xi), \xi \in [x_n, \alpha]$$

Dividing by $f'(x_n)$ which is not equal to zero in a nbd of α :

$$\frac{f(x_n)}{f'(x_n)} + (\alpha - x_n) = \alpha - \left[x_n - \frac{f(x_n)}{f'(x_n)} \right] = \alpha - x_{n+1} = -\frac{(\alpha - x_n)^2 f''(\xi)}{2f'(x_n)}$$
$$\therefore \varepsilon_{n+1} = \frac{1}{2} \varepsilon_n^2 \frac{f''(\xi)}{f'(x_n)} \quad \text{As } x_n \rightarrow \alpha, \quad \frac{\varepsilon_{n+1}}{\varepsilon_n^2} \rightarrow \frac{1}{2} \frac{f''(\xi)}{f'(\alpha)}$$

- Since $\varepsilon_{n+1} \propto \varepsilon_n^2$ the Newton-Raphson method is said to be quadratically convergent

Why did you make that assumption, well we said that all this epsilon n plus 1 which is equal to alpha minus x n plus 1 and epsilon n which is alpha minus x n, can be calculated to infinite precision right. So, there are no errors due to round off, with any finite precision machine right, any finite precision computer I know that when I compute epsilon n plus 1 is equal to alpha minus x n plus 1, I am not exactly going to get exactly alpha minus x n plus 1 if I going to be round off errors.

And what are those round off errors going to depend, well we looked at that lots of times in previously in the course, this rounds off errors are going to depend on my machine precision right on the precision of my computer right. So, everywhere the rounds off errors are unavoidable, so I cannot, so every time I do numerical computations, I have to leave that round off errors, but the important thing to remember is that this estimate that we have caught, assumes this quadratic convergence result assumes, that there are no round off errors right.

So, if there are significant round off errors am I going to get full quadratic convergence no, but if my round off errors are sufficiently small, am I going to get sufficiently close to quadratic convergence yes right. But, the it is I know I never going to get, full quadratic convergence because round off errors are never going to be 0.

(Refer Slide Time: 27:58)

Convergence of Newton Raphson

- The convergence criterion holds as long as round off errors in the calculations are small enough to be ignored
- Considering the update formula $x_{n+1} = x_n + h_n$, $h_n = -\frac{f(x_n)}{f'(x_n)}$
- It is clear that $f'(x_n)$ need only be computed to the same relative accuracy as $f(x_n)$
- As $x_n \rightarrow \infty$, $f(x_n) \rightarrow 0$ so its relative accuracy is low as x_n approaches the root. Hence it may not be necessary to compute  to unnecessary accuracy as x_n approaches the root

So, the convergence criterion holds as long as round off errors in the calculation as small enough to be ignored. Let us consider again the update formula $x_{n+1} = x_n + h_n$, $h_n = -\frac{f(x_n)}{f'(x_n)}$. It is clear that $f'(x_n)$ needs only be computed to the same relative accuracy as $f(x_n)$, this is a very important result, which has got very important implications, for particularly, formality dimensional approaches for Newton iterations.

What am I saying, I am saying that when you compute your update h_n , there is no point in computing $f'(x_n)$ to very, very high accuracy. If your $f(x_n)$ is not very accurate right because there is no point in computing only one part of this thing, very accurately while if $f(x_n)$ is not accurate that is going to put all the reason. So, my h_n is also going to be inaccurate right, so there is no point in computing the derivative with a high degree of accuracy, if I cannot compute my function value at an iterate with a sufficiently high accuracy.

Why when can I not compute my function value with a sufficiently high accuracy. When my $f(x_n)$ is when I am near the root right because near the root at near the root I know my function value is going to be 0 right. So, when I approach the root, my function value is going to become smaller and smaller, so as I become as the function value becomes smaller and smaller, it becomes harder and harder to compute it with sufficient accuracy right, because numbers becomes small. So, if I have numbers which are of the order of

10^{-5} and my machine precision is 10^{-6} , it becomes harder to compute $f(x_n)$ accurately right. So, there is going to be, more errors in the function evaluation closer to the root, so there is no point in computing the derivative with a great deal of accuracy, if my function value has got a lot of errors built into it.

Simply because my function, my iterate is sufficiently close to the root. So, my function value is very small, so these numbers are very small, so the round off is going to become more and more important right. So, it is clear that $f'(x_n)$ needs only be computed, to the same relative accuracy as $f(x_n)$ right. So, as x_n goes to infinity, as I go as and the number of iterations increases $f(x_n)$ goes to 0 because I am approaching closer and closer to the root.

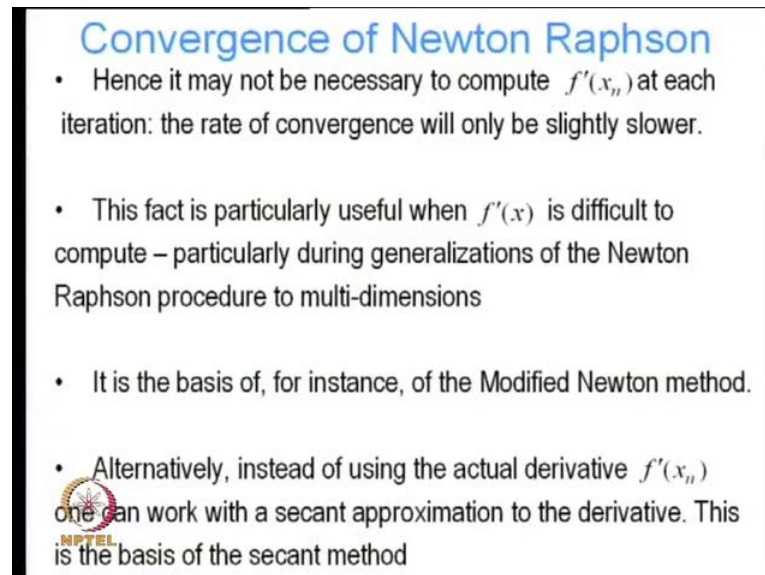

So, its relative accuracy is low as x_n approaches the root because $f(x_n)$ becomes closer and closer to 0. So, its relative accuracy is low, hence it may not be necessary to compute $f'(x_n)$ to unnecessary accuracy as x_n approaches the root. So, as I go close to the root, it may not be necessary to compute $f'(x_n)$ with a lot of accuracy sometimes, you can get away with not computing $f'(x_n)$ at every iteration, which is a very tremendous value, when we are looking at a multi dimensional problem.

We are computing $f'(x_n)$ basically, involving, evaluating an n by n matrix right and that is extremely expensive. So, if we can avoid doing that every iteration that saves a lot of computational time right hence, it may not be necessary to compute $f'(x_n)$ at each iteration, the rate of convergence will only be slightly slower. So, we do not need to converge to compute $f'(x_n)$, we do not need to compute the derivative at each iteration with suppose, I compute the derivative at n , I can use the same derivative that apply at $n+1$.

Why because the error I get by using the derivative at n , at $n+1$ is less or comparable with a error in the function value, error in the evaluation of the function itself right. So; that means, that error is not going to govern right. Hence, it may not be necessary to compute $f'(x_n)$ at each iteration, the rate of convergence will be slightly slower, so if we do this approximation, we do not compute the derivative at each iteration, we can be guarantee that we are not going to get quadratic convergence. But we if my error in f

prime x_n is not too high right, is not too high it is small compared to my it is comparable to my error in x_n , I am not going to get too far away from quadratic convergence right.

(Refer Slide Time: 33:11)

Convergence of Newton Raphson

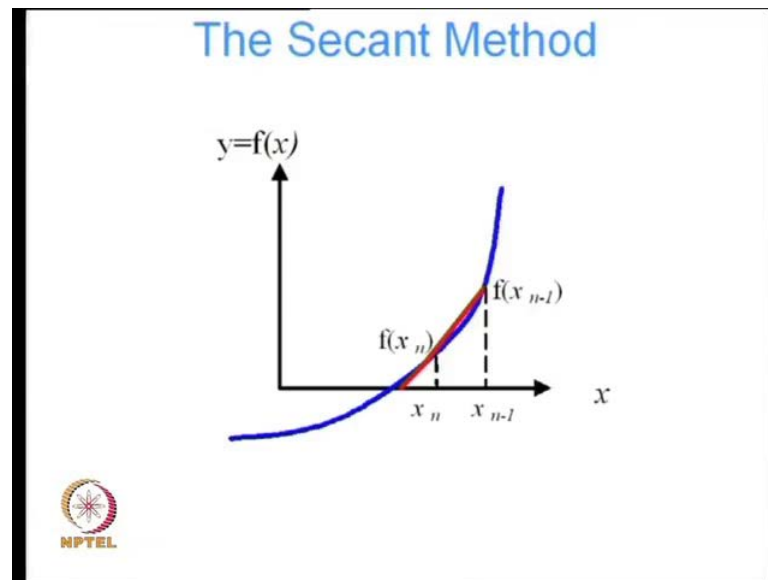

- Hence it may not be necessary to compute $f'(x_n)$ at each iteration: the rate of convergence will only be slightly slower.
- This fact is particularly useful when $f'(x)$ is difficult to compute – particularly during generalizations of the Newton Raphson procedure to multi-dimensions
- It is the basis of, for instance, of the Modified Newton method.
- Alternatively, instead of using the actual derivative $f'(x_n)$ one can work with a secant approximation to the derivative. This is the basis of the secant method

This fact is particularly useful when f' prime x is difficult to compute, particularly deriving generalizations of the Newton Raphson method to multiple dimensions as I mention, as soon as you go to multiple dimensions, when have f as a function of $x_1, x_2, x_3, \dots, x_n$ I have to compute the gradient matrix right. I have to compute terms like $\frac{\partial f}{\partial x_1}, \frac{\partial f}{\partial x_2}, \dots, \frac{\partial f}{\partial x_n}$ and so on and so forth. And terms at each iteration right that is very expensive.

So, if I can avoid doing that, if I can persist with my old tangent I can persist with my old derivative, then that saves a lot of computational expense right. And that is the basis or what is known as the modified Newton Raphson method, called multidimensional non linear equations right. So, the idea is becomes clear, if you look at a one dimensional problem.

So, alternatively that is what we wanted to say about the full Newton Raphson method. Let us switch over now to the secant method, when instant of actually evaluating the derivative, evaluating the tangent at $f(x)$ at x_n , I try to get an approximation to the tangent, how do I get an approximation to the tangent, by constructing a secant right. And I say that the slope of a function at x_n is given by the slope of a secant, which connects the function values at x_n and x_{n-1} right.

(Refer Slide Time: 34:49)

So, this is a picture I hope I have a picture of the secant method which is here, which says that earlier around in a Newton method I was actually constructing the accurate tangent here. Now, I do not construct the tangent, I see that I approximate the tangent by the secant, what is the secant it is the function value evaluated at an this point, minus the function value evaluated at that point, divided by the interval right.

(Refer Slide Time: 35:21)

The Secant Method

- The secant method can be derived from Newton Raphson's method by approximating the derivative $f'(x_n)$ as follows:
$$f'(x_n) \approx \frac{f(x_n) - f(x_{n-1})}{x_n - x_{n-1}} = \frac{f_n - f_{n-1}}{x_n - x_{n-1}}$$
- This leads to the following iteration scheme which needs information about the function values at two points to work (Newton Raphson only needs information at one point)
- The iteration scheme for the secant update is given by:
$$x_{n+1} = x_n + h_n, \quad h_n = -\frac{f_n(x_n - x_{n-1})}{f_n - f_{n-1}}, \quad f_n \neq f_{n-1}$$

The NPTEL logo is in the bottom left corner.

So, that is the secant method, which can be derived from Newton Raphson's method by approximating the derivative $f' x_n$ as follows. So, $f' x_n$ is approximately

equal to $f(x_n) - f(x_{n-1})$ divided by $x_n - x_{n-1}$, I am using this slightly simpler notation, I can write it as $f_n - f_{n-1}$ divided by $x_n - x_{n-1}$. So, this leads to the following iterative scheme, which needs the information about the function values at 2 points to work.

Remember, that for the Newton Raphson method I only needed evaluation I note only needed to evaluate the function, and its derivative at one point x_n . But, for the secant method to work, I need to evaluate the function at two points, at n and $n-1$ and this is the iteration scheme for the secant update which of course, resumes that $f_n - f_{n-1}$ is not equal to $f'(x_{n-1})$, we looked at that before.

(Refer Slide Time: 36:29)

The Secant Method

- Geometrically, x_{n+1} is determined as the abscissa of the point of intersection of the secant through $(x_{n-1}, f(x_{n-1}))$ and $(x_n, f(x_n))$ with the x -axis
- When $|x_n - x_{n-1}|$ is small, the slope of the secant $\frac{f_n - f_{n-1}}{x_n - x_{n-1}}$ will probably be determined with low relative accuracy
- It can however be shown that in general $|x_n - x_{n-1}| \gg |\alpha - x_n|$
- Hence the dominant contribution to the relative error in h_n comes from the evaluation of $f(x_n)$ particularly near the root, poor accuracy in the slope is of relatively less importance

So, geometrically x_{n+1} is determined as the abscissa of the point of intersection of the secant through $(x_{n-1}, f(x_{n-1}))$ and $(x_n, f(x_n))$ with the x axis.

(Refer Slide Time: 36:44)

So, basically it is determined my new iterate, is determined by the point of intersection, with the x axis right of the secant right.

(Refer Slide Time: 36:56)

The slide contains the following text:

- Geometrically, x_{n+1} is determined as the abscissa of the point of intersection of the secant through $(x_{n-1}, f(x_{n-1}))$ and $(x_n, f(x_n))$ with the x-axis
- When $|x_n - x_{n-1}|$ is small, the slope of the secant $\frac{f_n - f_{n-1}}{x_n - x_{n-1}}$ will probably be determined with low relative accuracy
- It can however be shown that in general $|x_n - x_{n-1}| \gg |\alpha - x_n|$
- Hence the dominant contribution to the relative error in h_n comes from the evaluation of $f(x_n)$ particularly near the root, poor accuracy in the slope is of relatively less importance

The NPTEL logo is visible in the bottom left corner.

Now, when bound of $x_n - x_{n-1}$ is small, the slope of this secant the slope of the secant being this right.

(Refer Slide Time: 37:06)

The Secant Method

- The secant method can be derived from Newton Raphson's method by approximating the derivative $f'(x_n)$ as follows:
$$f'(x_n) \approx \frac{f(x_n) - f(x_{n-1})}{x_n - x_{n-1}} = \frac{f_n - f_{n-1}}{x_n - x_{n-1}}$$
- This leads to the following iteration scheme which needs information about the function values at two points to work (Newton Raphson only needs information at one point)
- The iteration scheme for the secant update is given by:
$$x_{n+1} = x_n + h_n, \quad h_n = -\frac{f_n(x_n - x_{n-1})}{f_n - f_{n-1}}, \quad f_n \neq f_{n-1}$$

The slope of the secant being this, this slope when x_n minus x_{n-1} is small you can see that, this slope is going to be determined with relatively low accuracy right, there are going to be no errors in the evaluation of the slope.

(Refer Slide Time: 37:20)

The Secant Method

- Geometrically, x_{n+1} is determined as the abscissa of the point of intersection of the secant through $(x_{n-1}, f(x_{n-1}))$ and $(x_n, f(x_n))$ with the x-axis
- When $|x_n - x_{n-1}|$ is small, the slope of the secant $\frac{f_n - f_{n-1}}{x_n - x_{n-1}}$ will probably be determined with low relative accuracy
- It can however be shown that in general $|x_n - x_{n-1}| \gg |\alpha - x_n|$
- Hence the dominant contribution to the relative error in h_n comes from the evaluation of $f(x_n)$ particularly near the root, poor accuracy in the slope is of relatively less importance

However, it can be shown that a mod of x_n minus x_{n-1} is always greater than $|\alpha - x_n|$. So, the value of the two, value of the iterates between x_n and x_{n-1} is, always going to be much greater than $|\alpha - x_n|$. Hence, the dominant

contribution to the relative error in h_n comes from the evaluation of f of x_n particularly near the root. Poor accuracy in the slope is of relatively less importance.

As the dominant contribution to the relative error, comes from geometrically x_{n+1} is determined as the abscissa of the point of intersection of the secant to the x_{n-1} of x_n minus $1/n$ x_n f of x_n with the x axis. We can see, that one f mod of x_n minus x_n minus 1 is small, the slope of the secant will be determined with low relative accuracy, this term is going to become smaller and smaller. So, those errors are going to start becoming significant.

However, it can be shown that in general, mod of x_n minus x_n minus 1 is always going to be greater than α minus x_n . So, now, here, so the what does α minus x_n correspond to since, the dominant contribution to the relative error in h_n comes from the evaluation of f of x_n particularly the near the root. Poor accuracy in the slope is relatively less important why is that, well let us go back and take a look.

(Refer Slide Time: 39:15)

The Secant Method

- The secant method can be derived from Newton Raphson's method by approximating the derivative $f'(x_n)$ as follows:

$$f'(x_n) \approx \frac{f(x_n) - f(x_{n-1})}{x_n - x_{n-1}} = \frac{f_n - f_{n-1}}{x_n - x_{n-1}}$$
- This leads to the following iteration scheme which needs information about the function values at two points to work (Newton Raphson only needs information at one point)
- The iteration scheme for the secant update is given by:

$$x_{n+1} = x_n + h_n, \quad h_n = -\frac{f_n(x_n - x_{n-1})}{f_n - f_{n-1}}, \quad f_n \neq f_{n-1}$$

So, this error, the error due to this right this becoming small is going to be less important than the error due to the numerator becoming small right. Because, the error in the function is probably going to govern right because as the function goes to α , the error is going to the function values are going to become closer and closer to 0. So, here again as with the Newton Raphson the error in the function evaluation is going to govern.

(Refer Slide Time: 39:55)

The Secant Method

- Geometrically, x_{n+1} is determined as the abscissa of the point of intersection of the secant through $(x_{n-1}, f(x_{n-1}))$ and $(x_n, f(x_n))$ with the x-axis
- When $|x_n - x_{n-1}|$ is small, the slope of the secant $\frac{f_n - f_{n-1}}{x_n - x_{n-1}}$ will probably be determined with low relative accuracy
- It can however be shown that in general $|x_n - x_{n-1}| \gg |\alpha - x_n|$
- Hence the dominant contribution to the relative error in h_n comes from the evaluation of $f(x_n)$ particularly near the root, poor accuracy in the slope is of relatively less importance

Hence, the dominant contribution to the relative error in h_n comes from the evaluation of f of x_n particularly near the root, poor accuracy in the slope is of relatively less importance.

(Refer Slide Time: 40:09)

Error analysis for Secant Method

- To obtain an estimate of the error for the Secant method we consider Taylor series expansion of f about x_n as follows:

$$f(x) = f(x_n) + (x - x_n) \frac{f_n - f_{n-1}}{x_n - x_{n-1}} + \frac{(x - x_{n-1})(x - x_n)}{2} f''(\xi)$$

$\xi \in (x, x_n)$ (*)

In the above $f'(x_n)$ has been calculated using the secant approximation i.e. $f'(x_n) = \frac{f_n - f_{n-1}}{x_n - x_{n-1}}$.

If we ignore the remainder term and replace x by x_{n+1} we get:

$$f(x_{n+1}) = f_n + (x_{n+1} - x_n) \frac{f_n - f_{n-1}}{x_n - x_{n-1}}$$

Totally similarly to what we did for the Newton Raphson method, we would like to obtain an estimate of the error for the secant method. So, we consider an expansion of f about x_n , which is similar to a Taylor series expansion I have just said that it is not exactly a Taylor series expansion, you can see from the following it is called using

something which is known as Newton interpolation formula. But, it is sufficiently close to the Taylor series expansion I did not want to talk about Newton interpolation formula.

So, it is sufficiently close to the Taylor series expansion for you to get the idea. So, what we are doing is we are expanding this f of x right and we are expanding it about f of x_n right. So, we are writing f of x using Newton's interpolation formula, so we are writing f of x is equal to f of x_n plus $(x - x_n)$ times the slope which are now evaluating assuming the secant formula right. So, now, I am assuming the slope evaluated by the evaluating is using the secant formula.

And then there is this abdicite. In the abdicite, we will see it is different from the traditional Taylor series right why because now I am no longer using $(x - x_n)^2$ right, I am using $(x - x_n)$ times $(x - x_n)$ by factorial two times f'' of x_i where, x_i belongs to the which is the typical remainder term consists in a Taylor series, but only difference between a Taylor series and this term is that I am using $(x - x_n)$ times $(x - x_n)$. I am not using $(x - x_n)^2$ right.

This is known as Newton's interpolation formula. So, I have to take it for me un trust because we are not going to cover that in detail right because it can be written like this. So, in the above f' of x_n has been, you have evaluated the slope using the secant assumption that is we have used f of x_n is equal to f of n minus f of $n - 1$ divided by $x_n - x_{n-1}$. So, if we ignore the remainder term here, if we for the timing if I get the remainder term and we replace x by $x_n + 1$.

So, we replace x by $x_n + 1$ we get f of $x_n + 1$. So, we replace x here by $x_n + 1$ where f of $x_n + 1$ is equal to f of x_n which I write as f of n plus $(x_n + 1 - x_n)$ times f' of n minus f of $n - 1$ divided by $x_n - x_{n-1}$. Therefore, the time do not resume that my remainder is, so small that I can throw it away.

(Refer Slide Time: 43:13)

And since, in the secant method we know that $f(x_{n+1}) = 0$ right, why is that, let us go back and take a look at a secant method picture again. So, the assumption is that $f(x_{n+1}) = 0$ right.

(Refer Slide Time: 43:22)

Error analysis for Secant Method

- To obtain an estimate of the error for the Secant method we consider Taylor series expansion of f about x_n as follows:

$$f(x) = f(x_n) + (x - x_n) \frac{f_n - f_{n-1}}{x_n - x_{n-1}} + \frac{(x - x_{n-1})(x - x_n)}{2} f''(\xi)$$

$\xi \in (x, x_n)$ (*)

In the above $f'(x_n)$ has been calculated using the secant approximation i.e. $f'(x_n) = \frac{f_n - f_{n-1}}{x_n - x_{n-1}}$.

If we ignore the remainder term and replace x by x_{n+1} we get:

$$f(x_{n+1}) = f_n + (x_{n+1} - x_n) \frac{f_n - f_{n-1}}{x_n - x_{n-1}}$$

The NPTEL logo is in the bottom left corner of the slide.

So, secant method we assume that, so we have from this expression this term becomes 0.

(Refer Slide Time: 43:31)

Error analysis for Secant Method

And since in the secant method $f(x_{n+1}) = 0$, we have :

$$0 = f_n + (x_{n+1} - x_n) \frac{f_n - f_{n-1}}{x_n - x_{n-1}} \quad (**)$$

Substituting $x = \alpha$ in (*) and recalling $f(\alpha) = 0$, we get :

$$0 = f_n + (\alpha - x_n) \frac{f_n - f_{n-1}}{x_n - x_{n-1}} + \frac{(\alpha - x_{n-1})(\alpha - x_n)f''(\xi)}{2} \quad (***)$$

From (***) - (**): $(\alpha - x_{n+1}) \frac{f_n - f_{n-1}}{x_n - x_{n-1}} + \frac{(\alpha - x_{n-1})(\alpha - x_n)f''(\xi)}{2} = 0$

From the mean value theorem: $\frac{f_n - f_{n-1}}{x_n - x_{n-1}} = f'(\xi') \quad \xi' \in [x_{n-1}, x_n]$

$\therefore (\alpha - x_{n+1}) = \varepsilon_{n+1} = \frac{\varepsilon_{n-1}\varepsilon_n f''(\xi)}{2f'(\xi')}$

So, f_0 is equal to f of n plus x_n minus x_{n-1} times f of n minus f of $n-1$ divided by x_n minus x_{n-1} . And substituting x is equal to α , then we leave it like that and then we substitute x is equal to α in this expression and we call that f of α is equal to 0 because α is my root right. So, we have 0 is equal to f of x_n which I am writing as f of n plus x_n minus x_{n-1} becomes α minus x_n . So, as α minus x_n times f of n minus f of $n-1$ x_n minus x_{n-1} plus α minus x_{n-1} times α minus x_n by 2 times f double prime of ξ right.

So, α minus x_n minus 1 α minus x_n f double prime of ξ by 2 . So, you get that from my previous equation by substituting α and take remainder that f of α is equal to 0 . So, and then if I subtract this equation minus that equation, I have α minus x_n plus 1 times this, term this term cancels out f_n , f_{n-1} cancels out. So, at this term plus this term is equal to 0 right α minus x_n minus 1 α minus x_n f double prime ξ by 2 equal to 0 .

And then from the mean value theorem, I can write f_n minus f_{n-1} by x_n minus x_{n-1} is equal to the derivative f prime of ξ times f prime of ξ because this is in denominator right provided ξ prime belongs to x_{n-1} times x_n . So, I can write this expression as α minus x_n plus 1 , which is equal to by definition this is equal

to epsilon n plus 1. And let us look here, what is this alpha minus x n minus 1 it is epsilon n minus 1 right.

It is the error at the n minus 1'th iterate alpha minus x n is the error at the n'th iterate. So, as epsilon n minus 1 epsilon n times f double prime of xi divided by 2 f prime of xi, this way bringing this term to the denominator right, this term I am representing my f prime is xi prime and let me bring this to the denominator.

(Refer Slide Time: 46:45)

Error analysis for Secant Method

- From the above the secant method is seen to converge if $f'(\alpha) \neq 0$ and if $f(x)$ has a continuous second derivative
- Also as $x_{n-1} \rightarrow x_n$, $\epsilon_{n-1} \rightarrow \epsilon_n$, and the error formula for the Secant method becomes identical to the Newton Raphson method
- The order of convergence for the Secant method can be determined as follows:

When n is large, $\xi \approx \alpha$ and $\xi' \approx \alpha$ and

$$|\epsilon_{n+1}| \approx \frac{|f''(\alpha)| |\epsilon_n| |\epsilon_{n-1}|}{2|f'(\alpha)|} = C |\epsilon_n| |\epsilon_{n-1}|$$

So, what do we have, so from the above the secant method is seen to converge, if f prime of alpha is not equal to 0 and if f of x has a continuous second derivative why is that.

(Refer Slide Time: 46:57)

Error analysis for Secant Method

And since in the secant method $f(x_{n+1}) = 0$, we have :

$$0 = f_n + (x_{n+1} - x_n) \frac{f_n - f_{n-1}}{x_n - x_{n-1}} \quad (**)$$

Substituting $x = \alpha$ in (*) and recalling $f(\alpha) = 0$, we get :

$$0 = f_n + (\alpha - x_n) \frac{f_n - f_{n-1}}{x_n - x_{n-1}} + \frac{(\alpha - x_{n-1})(\alpha - x_n)f''(\xi)}{2} \quad (***)$$

From (***) - (**): $(\alpha - x_{n+1}) \frac{f_n - f_{n-1}}{x_n - x_{n-1}} + \frac{(\alpha - x_{n-1})(\alpha - x_n)f''(\xi)}{2} = 0$

From the mean value theorem: $\frac{f_n - f_{n-1}}{x_n - x_{n-1}} = f'(\xi'), \xi' \in [x_{n-1}, x_n]$

$\therefore (\alpha - x_{n+1}) = \varepsilon_{n+1} = \frac{\varepsilon_{n-1}\varepsilon_n f''(\xi)}{2f'(\xi')}$

This is formed to converge when f' prime of this is not equal to 0 right. So, the converge this is going to hold, only when this term is not going to be 0 right. So, again what is the criteria, that criteria is that there is sufficiently close to my root because only when it is sufficiently close to the root is my as I am guaranteed, that f' prime of alpha is not equal to 0.

Because, f' prime of x_n is f' prime of x_{i-1} is not equal to x_i I am always guarantee that f' prime of alpha is not equal to 0 because it is a by definition it is a simple root right why is it is a simple root f' prime of alpha is not equal to 0, but I am guaranteed that f' prime of x_{i-1} is not equal to 0, provided that x_{i-1} prime lies in a small neighborhood about alpha, where f' prime of x_n is not equal to 0.

Secant method is seen to converge if f' prime of alpha is not equal to 0 and if f of x has a continuous second derivative right. Since, f of x has a continuous second derivative f' prime of x must be continuous, which tells me that in a sufficiently small neighborhood around alpha, my derivative is not going to be 0. So, also as x_n tends x_{n-1} tends to x_n ε_{n+1} ε_n plus 1 ε_n prime x_1 is going to ε_n and this secant method is going to secant convergence formula is going to collapse to the Newton Raphson formula. Why is that let us go back and take a look again.

(Refer Slide Time: 48:46)

Error analysis for Secant Method

And since in the secant method $f(x_{n+1}) = 0$, we have :

$$0 = f_n + (x_{n+1} - x_n) \frac{f_n - f_{n-1}}{x_n - x_{n-1}} \quad (**)$$

Substituting $x = \alpha$ in (*) and recalling $f(\alpha) = 0$, we get :

$$0 = f_n + (\alpha - x_n) \frac{f_n - f_{n-1}}{x_n - x_{n-1}} + \frac{(\alpha - x_{n-1})(\alpha - x_n)f''(\xi)}{2} \quad (***)$$

From (***) - (**): $(\alpha - x_{n+1}) \frac{f_n - f_{n-1}}{x_n - x_{n-1}} + \frac{(\alpha - x_{n-1})(\alpha - x_n)f''(\xi)}{2} = 0$

From the mean value theorem: $\frac{f_n - f_{n-1}}{x_n - x_{n-1}} = f'(\xi') \quad \xi' \in [x_{n-1}, x_n]$

$\therefore (\alpha - x_{n+1}) = \varepsilon_{n+1} = \frac{\varepsilon_{n-1}\varepsilon_n f''(\xi)}{2f'(\xi')}$

So, when my iterations are converging my x_{n-1} and x_n are going to be very close to each other. So, my ε_{n-1} and ε_n are also going to be very close to each other. So, this term I can basically represent $\varepsilon_{n-1} \varepsilon_n$, I can write it as ε_n^2 and then I get back my Newton Raphson update formula.

(Refer Slide Time: 49:15)

Error analysis for Secant Method

- From the above the secant method is seen to converge if $f'(\alpha) \neq 0$ and if $f(x)$ has a continuous second derivative
- Also as $x_{n-1} \rightarrow x_n$, $\varepsilon_{n-1} \rightarrow \varepsilon_n$ and the error formula for the Secant method becomes identical to the Newton Raphson method
- The order of convergence for the Secant method can be determined as follows:

When n is large, $\xi \approx \alpha$ and $\xi' \approx \alpha$ and

$$|\varepsilon_{n+1}| \approx \frac{|f''(\alpha)| \varepsilon_n \varepsilon_{n-1}}{2|f'(\alpha)|} = C |\varepsilon_n| |\varepsilon_{n-1}|$$

What is the order of convergence for the secant method, well we can find it out quite easily. Suppose, when n is large then x_i is approximately equal to α and x_i' is approximately equal to α why is that well.

(Refer Slide Time: 49:31)

Error analysis for Secant Method

And since in the secant method $f(x_{n+1}) = 0$, we have :

$$0 = f_n + (x_{n+1} - x_n) \frac{f_n - f_{n-1}}{x_n - x_{n-1}} \quad (**)$$

Substituting $x = \alpha$ in (*) and recalling $f(\alpha) = 0$, we get :

$$0 = f_n + (\alpha - x_n) \frac{f_n - f_{n-1}}{x_n - x_{n-1}} + \frac{(\alpha - x_{n-1})(\alpha - x_n)f''(\xi)}{2} \quad (***)$$

From (***) - (**): $(\alpha - x_{n+1}) \frac{f_n - f_{n-1}}{x_n - x_{n-1}} + \frac{(\alpha - x_{n-1})(\alpha - x_n)f''(\xi)}{2} = 0$

From the mean value theorem: $\frac{f_n - f_{n-1}}{x_n - x_{n-1}} = f'(\xi') \quad \xi' \in [x_{n-1}, x_n]$

$\therefore (\alpha - x_{n+1}) = \varepsilon_{n+1} = \frac{\varepsilon_{n-1}\varepsilon_n f''(\xi)}{2f'(\xi')}$

What is ξ , ξ prime belongs to x_{n-1} , x_n right then when we are close to the solution both x_{n-1} and x_n are also very close to α right. So, I can replace $f'(\xi)$ as $f'(\alpha)$, sufficiently close to the root I can replace the $f'(\xi)$ in this formula, my $f'(\alpha)$. Similarly, I can replace $f''(\xi)$, ξ again sufficiently close to the root I can replace it by its value of the root right.

Because, it is continuous right I can and if I am sufficiently close to the root if even if I am not exactly at the root the value is going to be infinitesimally different from the value of α because the function is continuous right. So, I can replace these values by the values of α .

(Refer Slide Time: 50:36)

Error analysis for Secant Method

- From the above the secant method is seen to converge if $f'(\alpha) \neq 0$ and if $f(x)$ has a continuous second derivative
- Also as $x_{n-1} \rightarrow x_n$, $\varepsilon_{n-1} \rightarrow \varepsilon_n$ and the error formula for the Secant method becomes identical to the Newton Raphson method
- The order of convergence for the Secant method can be determined as follows:

When n is large, $\xi \approx \alpha$ and $\xi' \approx \alpha$ and

$$|\varepsilon_{n+1}| \approx \frac{|f''(\alpha)| |\varepsilon_n| |\varepsilon_{n-1}|}{2|f'(\alpha)|} = C |\varepsilon_n| |\varepsilon_{n-1}|$$

And in that case, I can get this. So, I am just taking mod of both sides, I am taking mod of both sides of this expression right. So, mod of epsilon n plus 1 is approximately equal to mod of f double prime mod of epsilon n mod of epsilon n minus 1 divided by twice mod of f prime of alpha. So, this I can treat it as a constant f double prime of alpha because the root is known the derivative of the function, double derivative of the function at a certain point they are constants right. So, I can replace this term by a constant and write it as mod of epsilon n plus 1 is approximately equal to C times mod of epsilon n times mod of epsilon n minus 1. So, let us you how we can use it to find the order of convergence.

(Refer Slide Time: 51:29)

Error analysis for Secant Method

Suppose $|\varepsilon_{n+1}| = K|\varepsilon_n|^p$ $|\varepsilon_n| = K|\varepsilon_{n-1}|^p$

Substituting in $\varepsilon_{n+1} \approx C|\varepsilon_n||\varepsilon_{n-1}|$ we get :

$K|\varepsilon_n|^p \approx C|\varepsilon_n|K^{-1/p}|\varepsilon_n|^{1/p}$. This relation can only be true if

$$1 + \frac{1}{p} = p \text{ i.e. } p = \frac{1}{2}(1 \pm \sqrt{5}) \text{ and } C = K^{1+1/p} = K^p$$

Since $p = \frac{1}{2}(1 - \sqrt{5})$ gives an imaginary number not useful

for determining the order of convergence, we get : $p = \frac{1}{2}(1 + \sqrt{5})$

Thus $p = 1.618 < 2$, hence the Secant method has less than quadratic convergence, unlike the Newton Raphson method

So, let us suppose that my order of convergence is P, then I can I know that I can write mod of epsilon n plus 1 as come constant times mod of epsilon into the power P. And again, we can write mod of epsilon n as K is of same constant, times mod of epsilon n minus 1 to the power P right because this is the order of convergence of my algorithm right.

So, this asymptotic value k and that order of convergence is going to be the same whether, I am looking at n plus 1 or n right. So, let us substitute use these expressions and substitute it in my this expression, if I substitute that in that expression what do I get, I get replacing mod of epsilon n plus 1 is K mod of epsilon into the power P is approximately equal to C times mod of epsilon n. And then mod of epsilon n minus 1 I have again replace by mod of epsilon n to the power 1 by P and K to the power minus 1 by P.

I taking the P'th root of both sides of this equation right. Now, this relationship can only be true look at the powers of mod of epsilon n, so in this side I have mod of epsilon n rise to the power P and this side has mod of epsilon rise to the power 1 and mod of epsilon n rise to the power 1 by P. So, this is only going to be true, if 1 plus 1 by P is approximately equal to P right, if 1 plus 1 by P is equal to P, then this equation is going to be satisfied right.

So, what does this give me, this gives me a quadratic equation in P, it is a quadratic equation in P I find the roots of that right, P is equal to half 1 plus minus root of 5 right. So, if I have something if I have P negative, it is not really an imaginary number if I take this negative sign, then I get a negative value for P which does not tell me matched out convergence. So, I take the positive root of this right, half plus 1, 1 plus root of 5, which gives me P is equal to 1.618 right.

And again, if we look at the constants what do we have, we have K here, we have C here, and we have K to the power minus 1 by P. So, what does this tells me, this tells me that K to the power 1 plus 1 by P, must be equal to C and I know that 1 plus 1 by P is equal to P. So, C must be equal to K to the power P right, so from evaluating this expression, we can find out that P is equal to 1.618, which is less than 2, which basically means that the secant method has less than quadratic convergence, unlike the Newton Raphson method right. So, it is not linear convergence, it is P is not equal to 1, P is not equal to 2, P is somewhere in between right. So, that is what is happens for the secant method.

(Refer Slide Time: 54:55)

Generalized Iteration Method

- Both Newton Raphson and Secant methods can be regarded as special instances of a general theory of iteration methods where x_{n+1} is determined by function values and values of the derivative of $f(x)$ at 'm' points i.e.:

$$x_{n+1} = \phi(x_n, x_{n-1}, \dots, x_{n-m})$$

- The function ϕ is known as the iteration function and is obtained by re-writing $f(x) = 0$ as $x = \phi(x)$
- When $m=1$, we recover $x_{n+1} = \phi(x_n)$: a one point iteration

So, that is all I have to talk about one dimensional equations and finding roots of one dimensional equations. That in reality in most engineering problems, in most engineering problems, in most civil engineering problems, we deal with multidimensional situations right. So, we deal with non linear equations, which are not one dimensional that is f is no longer a function of x only, f is a function of x 1 through may be n variables and we have

n equations we have n equations and n unknowns and each of those equations is non linear.

So, we have to find ways of solving those systems that non linear equations, it turns out the ideas that we have developed for one dimensional equations, they are very useful to carry over for non linear, for multidimensional equations as well. Particularly the idea that we talked about relating to the, relative accuracy in the derivative right I mean the relative accuracy in the, there is no point in achieving a in calculating the derivative with a high level of accuracy.

Then my function evaluation, when my function has a significant amount of error right. So, those things become very useful, when we generalize to multiple dimensions, so we are going to continue with that in next class.

Thank you.
