Sources of errors in a numerical algorithm

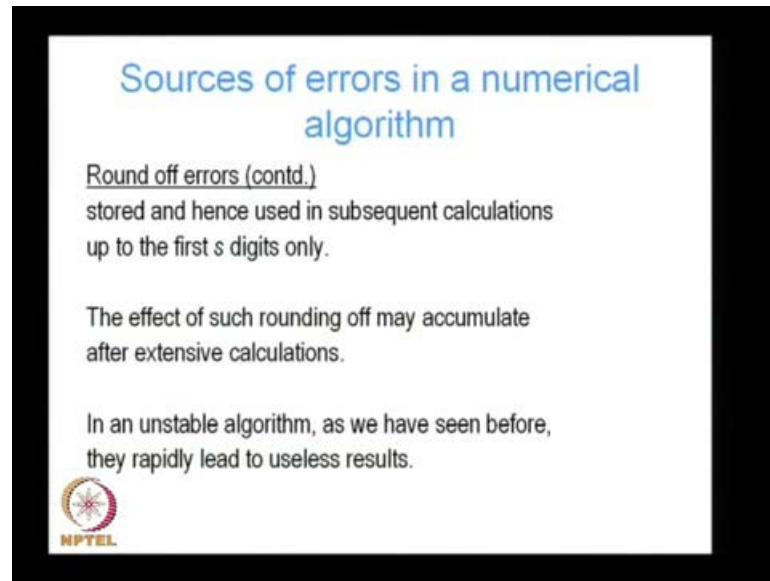

Round off errors
All calculating devices perform finite precision arithmetic i.e. they cannot handle more than a specified number of digits.

Hence, if a computer can handle numbers up to 's' digits only, then the product of two such numbers, which in reality have $2s$ or $2s-1$ digits, can only be

Since, civil engineering we are going to talk about Error Analysis. First we want to talk about the sources of errors in a numerical algorithm, the first type of error we are going to talk about a round off errors. All calculating devices perform finite precision arithmetic that is, they cannot handle more than a specified number of digits. For instance, if a computer can handle numbers up to s digits only where s is a number then the product of two such numbers which in reality have $2s$ or $2s$ minus 1 digits. For instance if I have a number that has two digits for instance 12 if I multiplied by another number which has two digits for instance 12 again I get a number with 144 digits, which has got two times 2 minus 1 that is $2s$ minus 1 that is three digits can one.

(Refer Slide Time: 01:34)

Sources of errors in a numerical algorithm

Round off errors (contd.)
stored and hence used in subsequent calculations up to the first s digits only.

The effect of such rounding off may accumulate after extensive calculations.

In an unstable algorithm, as we have seen before, they rapidly lead to useless results.

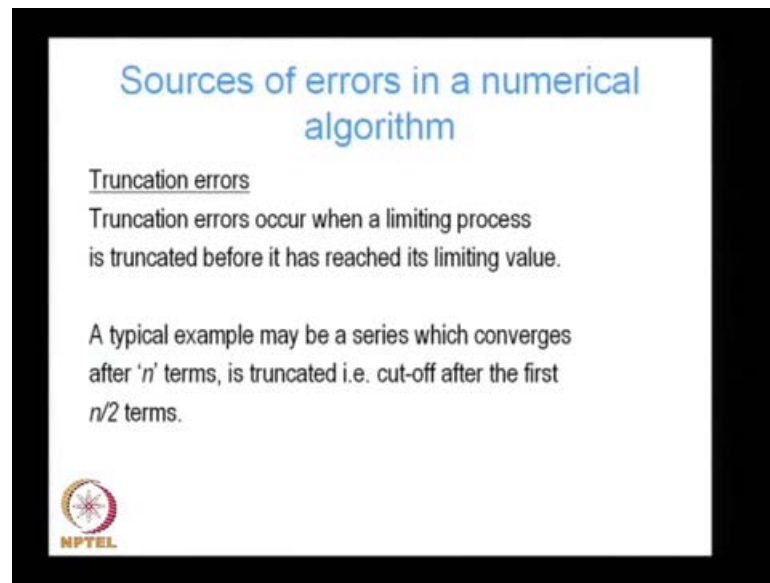

NPTEL

For a computer however, we will only store it as in s digit number and use it in subsequent calculation using only the first 8 digits of that number. The effect of such rounding off may accumulate after extensive calculations, for instance if we are doing a series of products every time we do a product we instead of storing $2s$ digits if each number has s digits instead of storing $2s$ digits we are storing s digits.

So, each time we are losing a certain accuracy, so each time we are introducing inaccuracy and as this inaccuracy is by law they made these may become significant. In an unstable algorithm as we have seen before in our first lecture, this accumulation of this round off errors lead to useless and or grossly in accurate results.

(Refer Slide Time: 02:33)

Sources of errors in a numerical algorithm

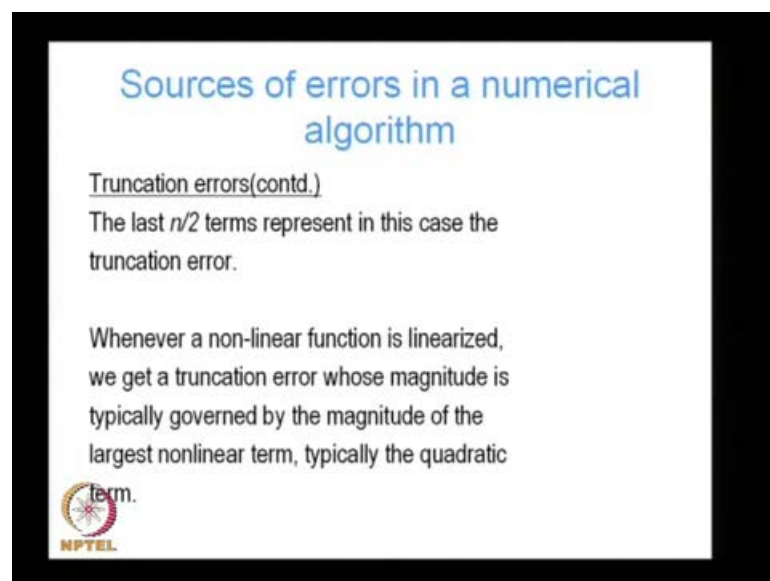

Truncation errors
Truncation errors occur when a limiting process is truncated before it has reached its limiting value.

A typical example may be a series which converges after ' n ' terms, is truncated i.e. cut-off after the first $n/2$ terms.

So, first type of errors we talked about was round off errors, the second type of error we are going to talk about are known as truncation errors. Truncation errors occur when a limiting process is truncated before it has reached its limiting value, a typical example of this may be a series which of suppose converges after n terms which suppose we truncated that is we cut it off after the first n by 2 terms. So, if the series converges after n equal to suppose 10 terms suppose we cut it off after we compute only five terms in the series that is n by 2 terms.

(Refer Slide Time: 03:24)

Sources of errors in a numerical algorithm

Truncation errors(contd.)
The last $n/2$ terms represent in this case the truncation error.

Whenever a non-linear function is linearized, we get a truncation error whose magnitude is typically governed by the magnitude of the largest nonlinear term, typically the quadratic term.

In that case the last n by 2 terms represent the truncation error the last five terms in this series, where n is equal to 10 are not being accounted for, so they represent the truncation error. For instance, whenever a non-linear function is linearize we get a truncation error, whose magnitude is typically governed by the magnitude of the largest non linear term typically the quadratic term. When we linearize the function we ignore all terms which higher than, linear higher than first ordered term. And if the first non linear term is the quadratic term then the error has also dimension are also second order.

(Refer Slide Time: 04:15)

Sources of errors in a numerical algorithm

Truncation errors(contd.)

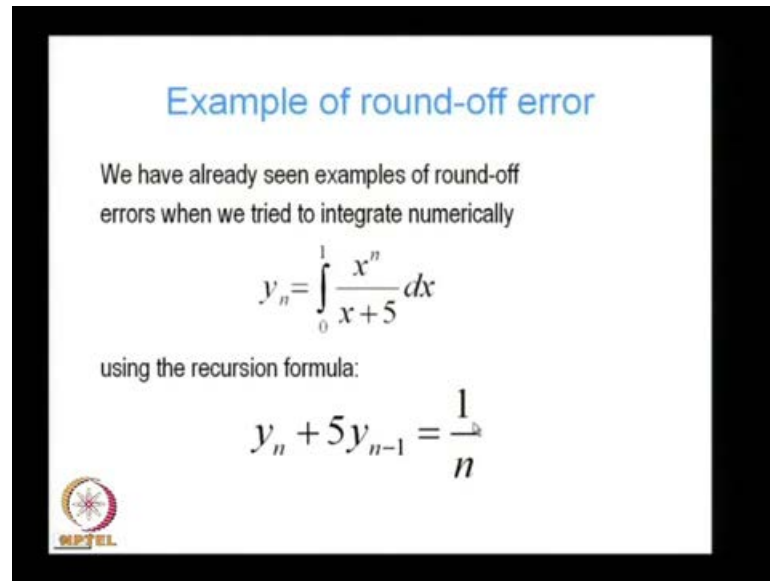

Nonlinear function of x , $f(x)$ is linearized about x_0 :

$$f(x) = f(x_0) + \left. \frac{df}{dx} \right|_{x_0} (x - x_0) + \underbrace{\text{quadratic terms}}_{\text{truncation error}}$$

For instance here, if we are considering a non linear function of x f of x which is linearized about the value x_0 , we can write f of x is equal to f of x_0 plus the derivative of x f with respect to x evaluated at x_0 times x minus x_0 , which is the linear term plus the quadratic terms, which represent the truncation error.

(Refer Slide Time: 04:50)

Example of round-off error

We have already seen examples of round-off errors when we tried to integrate numerically

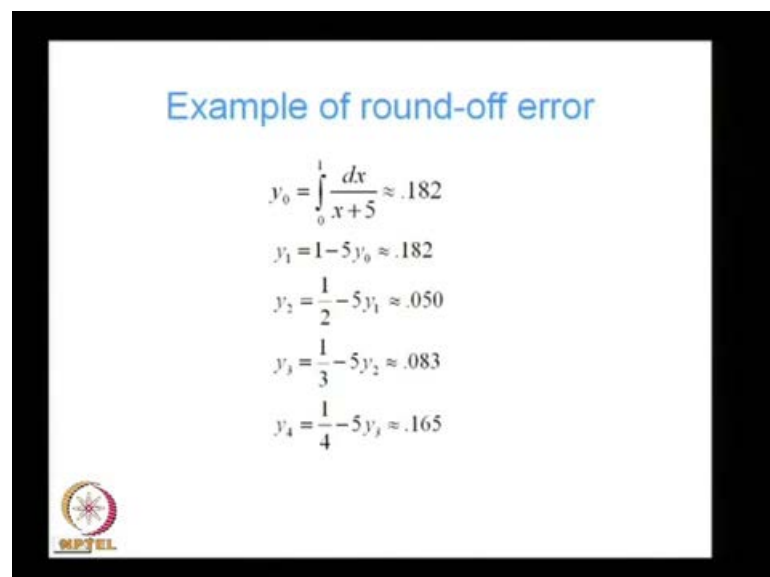

$$y_n = \int_0^1 \frac{x^n}{x+5} dx$$

using the recursion formula:

$$y_n + 5y_{n-1} = \frac{1}{n}$$

Examples, next we will consider examples of round off and truncation errors we have already seen examples of round off errors, when we tried to integrate numerically y_n equal to x^n by x plus 5 over the intervals 0 to 1. When we tried to evaluate this integral for various values of n using the following the recursion formula $y_n + 5y_{n-1}$ is equal to y_1 by n .

(Refer Slide Time: 05:28)

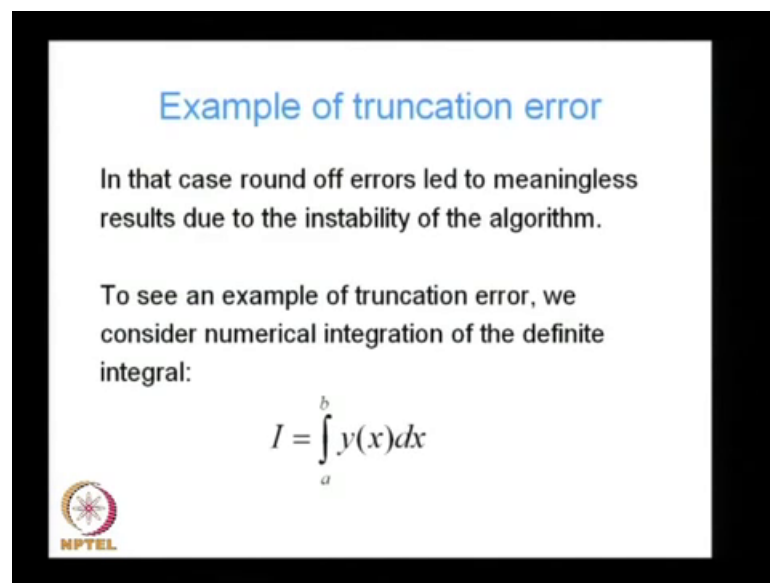

Example of round-off error

$$y_0 = \int_0^1 \frac{dx}{x+5} \approx .182$$
$$y_1 = 1 - 5y_0 \approx .182$$
$$y_2 = \frac{1}{2} - 5y_1 \approx .050$$
$$y_3 = \frac{1}{3} - 5y_2 \approx .083$$
$$y_4 = \frac{1}{4} - 5y_3 \approx .165$$

In our first lecture, we found that inherent in stability of this numerical algorithm let to accumulation of the round off errors and very quickly may be even after just five

iterations we were getting results which had no relationship with the reality, that the results were totally wrong. We started with y_0 equal to 0.182 and the by the time we reach to y_4 we reached we got a value of 0.165, which was totally different from the true solution and this we found was because of, the inherent instability of the numerical algorithm. We used which allowed these round off errors to pile up and lead to be essentially meaningless results.

(Refer Slide Time: 06:17)

Example of truncation error

In that case round off errors led to meaningless results due to the instability of the algorithm.

To see an example of truncation error, we consider numerical integration of the definite integral:

$$I = \int_a^b y(x) dx$$

 NPTEL

In that case round off errors let to meaningless results due to the instability of the algorithm. To see an example of truncation error, we consider numerical integration of the definite integral y of x integrated between the limits a and b .

(Refer Slide Time: 06:42)

Example of truncation error

Suppose we use the secant approximation to evaluate the integral.

The secant method, we recall, consists of approximating the non linear function by straight lines connecting successive function values.

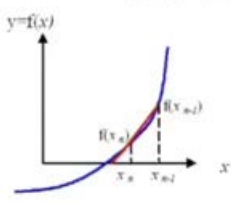

Suppose we use the secant approximation to evaluate this integral. We recall from our last lecture that the secant method, consists of approximating the non-linear function by straight lines connecting successive function values.

(Refer Slide Time: 07:01)

Example of truncation error

Given the iterates x_n and x_{n-1} as well as the function values $f(x_n)$ and $f(x_{n-1})$ we find the next iterate using the following update formula:

$$x_{n+1} = x_n - f(x_n) \frac{x_n - x_{n-1}}{f(x_n) - f(x_{n-1})}$$

That is given the iterates x_n and x_{n-1} as well as the function values $f(x_n)$ and $f(x_{n-1})$ we find the next iterate using the following update formula $x_{n+1} = x_n - f(x_n) \frac{x_n - x_{n-1}}{f(x_n) - f(x_{n-1})}$. Graphically this means that this non-linear curve in blue is approximated by

straight lines joining points on the curve, which represent each iterate and its value and its function value.

(Refer Slide Time: 07:55)

Example of truncation error

We assume that the 'step size' is constant i.e. successive values of the independent variable x e.g. x_n and x_{n-1} differ by the constant step size ' h '

Thus the area between the curve $y=f(x)$ and the x axis is approximated with the sum $I(h)$ of the areas of a series of trapezoids, each with a const. base width of h .

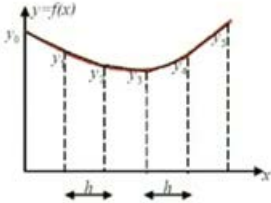

We further assume that in our iteration proceed a using the secant algorithm the steps size we use is constant that is successive values of the independent variable x for example, x_n and x_{n-1} differ by a constant step size h . Thus the area between the curve y is equal to f of x and the x axis is approximated with the sum i of h of the areas of a series of trapezoids, each with the constant base width of h .

(Refer Slide Time: 08:39)

Example of truncation error

Hence the name 'trapezoidal rule' for this integration scheme

That is this area between the curve and the x axis is approximated by these trapezoids, each trapezoid representing an iteration in our secant update algorithm. So, each trapezoid has of course, constant base h since we are we are iterating with a constant step size and since, the total area under the curve is obtained by summing up the area of these trapezoids we use the name trapezoidal rule for this integration scheme.

(Refer Slide Time: 09:19)

Example of truncation error

$$I(h) = \frac{1}{2}(y_0 + y_1)h + \frac{1}{2}(y_1 + y_2)h$$

$$+ \frac{1}{2}(y_2 + y_3)h + \frac{1}{2}(y_3 + y_4)h$$

$$+ \frac{1}{2}(y_4 + y_5)h$$

The 'truncation error', the error due to the approximation of the nonlinear variation of $y=f(x)$ with a series of 'linear variations' is of the order h^2 when h is small.

Let us see what the trapezoidal rule means, if we have five intervals for evaluating our function y is equal to f of x between these two limits. In that case, we can write i of h is equal to sum of the first trapezoid plus the sum of the second trapezoid plus third and the 4th and the fifth trapezoid and as you can see the area of the base in each trapezoid is the same the constants step size h while the sum of the parallel sides is given by y_0 plus y_1 .

The truncation error, the error due to the approximation of the non-linear variation of y which is equal to f of x with a series of linear variation in our case these trapezoids is of the order of h square when h is small.

(Refer Slide Time 10:30)

Reducing truncation error

This means that the error $I - I(2h)$ for a step size of $2h$ is very nearly proportional to $4h^2$ while the error $I - I(h)$ for a step size of h is very nearly proportional to h^2 .

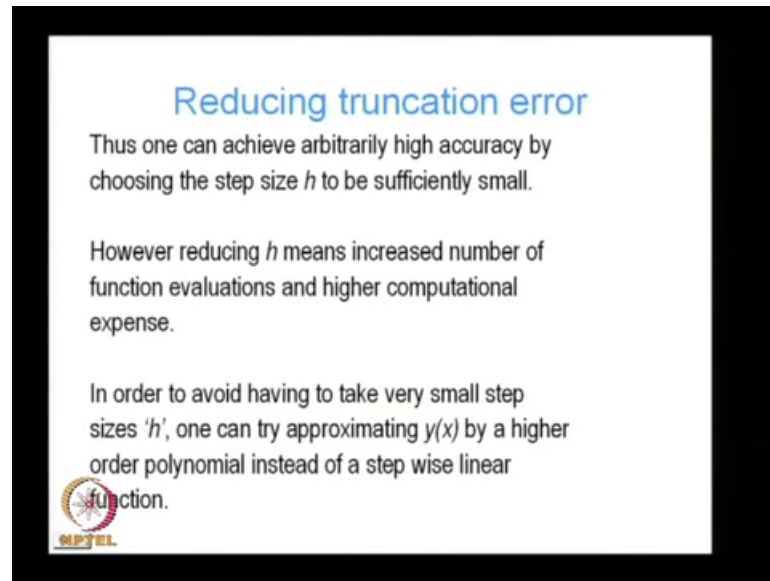

Hence:

$$\frac{I - I(h)}{I - I(2h)} = \frac{1}{4}$$

Thus, what it means is that the error between i and $i(2h)$ where i is the exact value of the integral and i within brackets $2h$ is the result of our trapezoidal integration scheme where we have used the step size of $2h$ is going to vary proportionally with respect to the step size.

So, it is going to be very nearly proportional to $4h^2$ while, if the step size is h the error between the exact value i and when numerically evaluated value using the trapezoidal rule with the constant step size of h i minus $i(h)$ is very nearly proportional to h^2 . Hence, if we take a ratio of the errors i minus $i(h)$ divided by i minus $i(2h)$ we see that this ratio goes as h^2 by $4h^2$ h^2 h^2 cancels out and we get a ratio of $1/4$.

(Refer Slide Time: 11:40)

Reducing truncation error

Thus one can achieve arbitrarily high accuracy by choosing the step size h to be sufficiently small.

However reducing h means increased number of function evaluations and higher computational expense.

In order to avoid having to take very small step sizes ' h ', one can try approximating $y(x)$ by a higher order polynomial instead of a step wise linear function.

 NPTEL

Thus we see that by reducing the step size by half we are getting an error which is just one 4th of the error with the step size with the previous step size. So, we reduce the error reduce the step size from h to $2h$ and our error goes down by a factor of 4. We can see from this that we can achieve arbitrarily high accuracy by choosing the step size h to be sufficiently small, as we keep on reducing h the error is going to become smaller and smaller and the error is going to reduce quadratically that with step size h

However, reducing h means increased number of function evaluations and higher computational expense. This is because, if interval over which we had computing on the integral remains the same as we reduce the step size we have more function evaluation we have to evaluate the function at more points and this begins to greater computational expense.

In order to avoid having to take very small step sizes h , instead of using a linear approximation which we did here one can try approximating y of x by higher order polynomial for instance instead of approximating it y of x by a linear polynomial we can use higher order polynomial for instance a quadratic function.

(Refer Slide Time: 13:14)

Reducing truncation error

For instance the area under the curve $y(x)$ may be evaluated by approximating $y(x)$ with piecewise quadratic functions.

That would be an example of polynomial or ' p ' refinement.

Continuing with the secant (piece-wise linear) approximation while reducing the size of the step ' h ' is an example of ' h ' refinement.

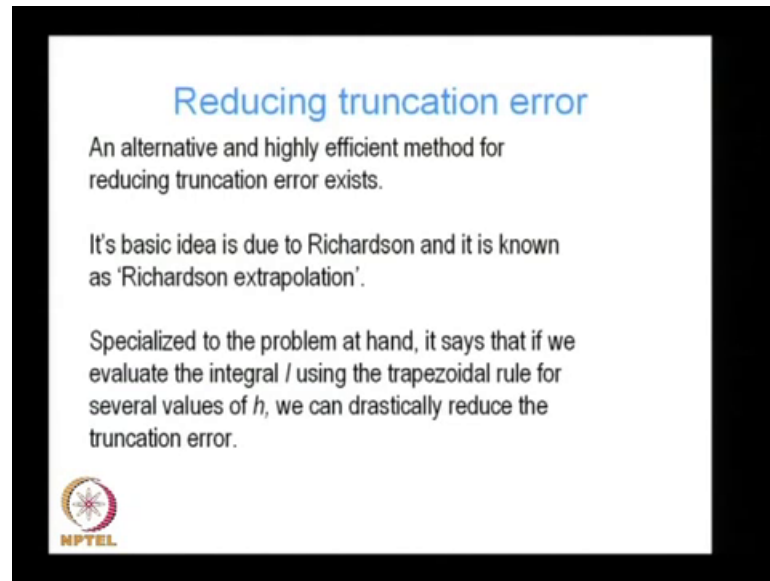

NPTEL

Quadratic polynomial for instance the area under the curve y of x may be evaluated by approximating y a y x with piece wise quadratic function. That would be an example of polynomial or p refinement, where we have approximated the function y of x by a higher order polynomial 9 in this case a quadratic polynomial similarly, we can use cubic quadratic polynomials to approximate the function y over f x over are intervals over are step sizes.

Alternatively, if we continue with our secant that is our piece wise linear approximation while reducing the size of the step h that would be an example of h refinement, these are very common ideas in numerical analysis polynomial refinement and step size refinement or mesh size refinements. So, these are the two main types of refinements which people use to get more accurate solutions.

(Refer Slide Time: 14:30)

Reducing truncation error

An alternative and highly efficient method for reducing truncation error exists.

It's basic idea is due to Richardson and it is known as 'Richardson extrapolation'.

Specialized to the problem at hand, it says that if we evaluate the integral / using the trapezoidal rule for several values of h , we can drastically reduce the truncation error.

However instead of using either h or p refinement there is an alternative and highly efficient method for reducing the truncation error, its basic idea is due to richardson and it is known as richardson extrapolation. In our particular problem and where we want to evaluated integral within a certain bounds what it means is that if we use if we evaluate the integral using the trapezoidal rule if instead of reducing h reducing the step size h or increasing the order of our polynomial approximation.

If we cut persist with our linear approximation that is we persist with the trapezoidal rule, but use the trapezoidal rule several times that is for several values of h and we combined the values of the integral obtained using the several values of h , we can drastically reduce the truncation error.

(Refer Slide Time: 15:33)

Reducing truncation error

Recall that the trapezoidal approximation to:

$$I = \int_a^b y(x) dx$$

has an error approximately proportional to the square of the step size h .

Therefore by evaluating the integral for two step sizes h and $2h$ and combining the results, we can come up with a vastly improved solution.

Let us recall that the trapezoidal approximation to I is equal to integral of y of x evaluated within the bounds a to b has an error approximately proportional to the square of the step size h . Therefore, while evaluating the integral for two step sizes h and $2h$ and combining the results, we can come up with a vastly improved solution as we will see in the next slide.

(Refer Slide Time: 16:07)

Reducing truncation error

$$I(h) - I \approx Kh^2 \text{ and } I(2h) - I \approx K4h^2$$

where K is a proportionality constant

$$\therefore 4(I(h) - I) \approx I(2h) - I$$
$$\therefore 3I \approx 4I(h) - I(2h)$$

which leads to $I \approx I(h) + \frac{1}{3}[I(h) - I(2h)]$

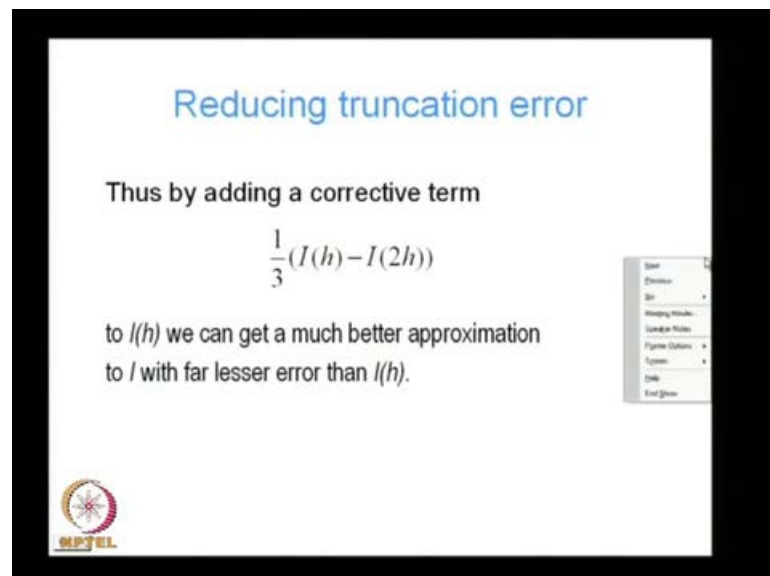

Since the error is of the order of h^2 we recall that I of h which is I this is the integral which is evaluated using the trapezoidal approximation with step size h , differs

from the true solution by h^2 . So, the error is of order h^2 and can be written as $k h^2$ where k is a proportionality constant since the error is proportional to h^2 we can write that the error is approximately equal to the proportionality constant k times h^2 .

Similarly, if we reduce the step size if we use a step size of $2h$ then in that case the difference between $I(2h)$ where I is the error with the step size of $2h$ and I_h is the integral with the step size of h and I is the exact value the difference between these 2 values is given by k times $4h^2$.

Subtracting these 2 we see that $4I_h - I$ is approximately equal to $I(2h)$ minus $4I_h$ that is equal to $4k h^2$ minus $I(2h)$ is again equal to k times $4h^2$, so these 2 are equal. So, this gives me an equation for the exact value of the integral which is I if we solve this equation for I we get I is approximately equal to $4I_h - I(2h)$, the integral evaluated with the step size of h minus $I(2h)$ that is the integral evaluated with the step size $2h$. This leads me to the expression that the exact value of the integral is approximately equal to $I_h + \frac{1}{3}(I_h - I(2h))$.

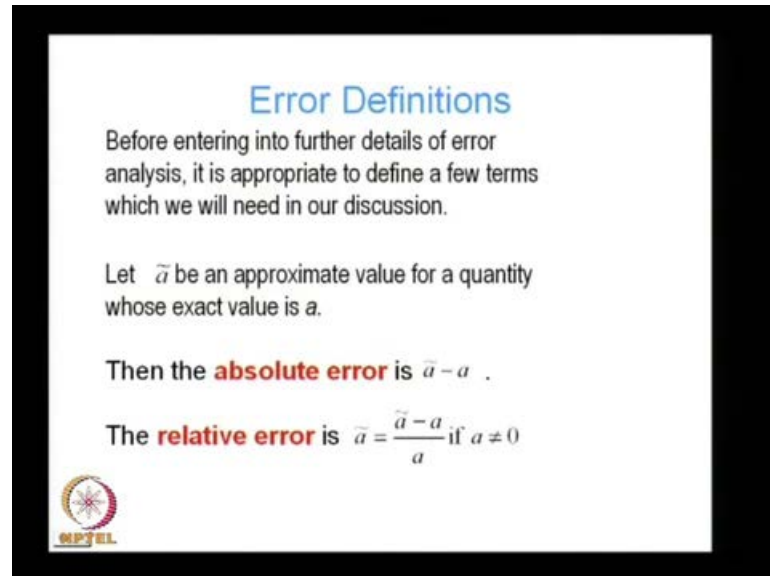

(Refer Slide Time: 18:16)

Thus by adding the corrective term $\frac{1}{3}(I_h - I(2h))$ to I_h we get a much better approximation to I with far lesser error than I_h that is, by adding this additional term which is one third times $I_h - I(2h)$ we get an error we get a

solution we get a value of the integral which is much closer to the true solution than h itself.

(Refer Slide Time: 18:55)

Error Definitions

Before entering into further details of error analysis, it is appropriate to define a few terms which we will need in our discussion.

Let \tilde{a} be an approximate value for a quantity whose exact value is a .

Then the **absolute error** is $\tilde{a} - a$.

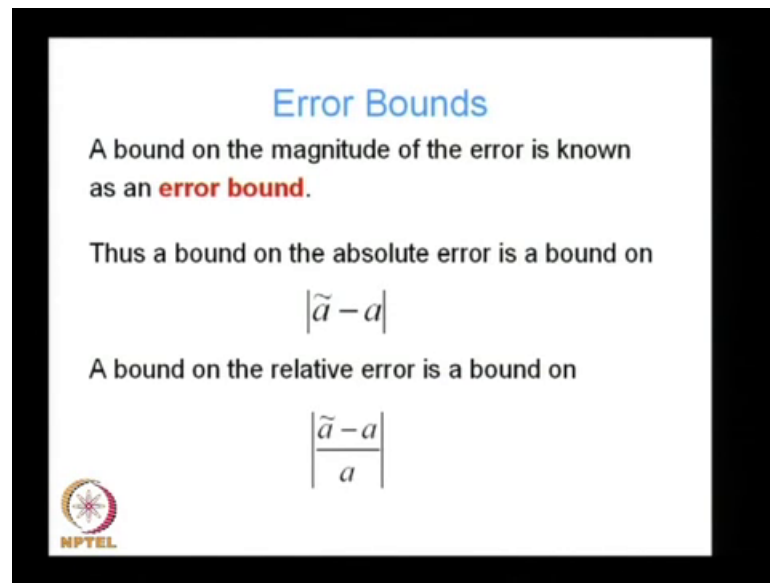

The **relative error** is $\tilde{a} = \frac{\tilde{a} - a}{a}$ if $a \neq 0$

Before entering into further details of error analysis, we would like to define a few terms which will need in our discussion. First terms that we want to define we let we let two types of errors if we denote a tilde to be an approximate value for a , quantity whose exact value is a then we define the absolute error in a is given by the approximate value minus to the true value that is the absolute error is $\tilde{a} - a$, the relative error on the other hand is given by $\tilde{a} = \frac{\tilde{a} - a}{a}$ if $a \neq 0$.

This of course, assumes that a is not equal to 0 if a is equal to 0 we cannot define the relative error. So, the absolute error is just the numerical solution \tilde{a} minus the true solution a where the relative error is the numerical solution \tilde{a} minus the true solution a divided by the true solution a assuming of course, that the true solution is not equal to 0.

(Refer Slide Time: 20:21)

Error Bounds

A bound on the magnitude of the error is known as an **error bound**.

Thus a bound on the absolute error is a bound on

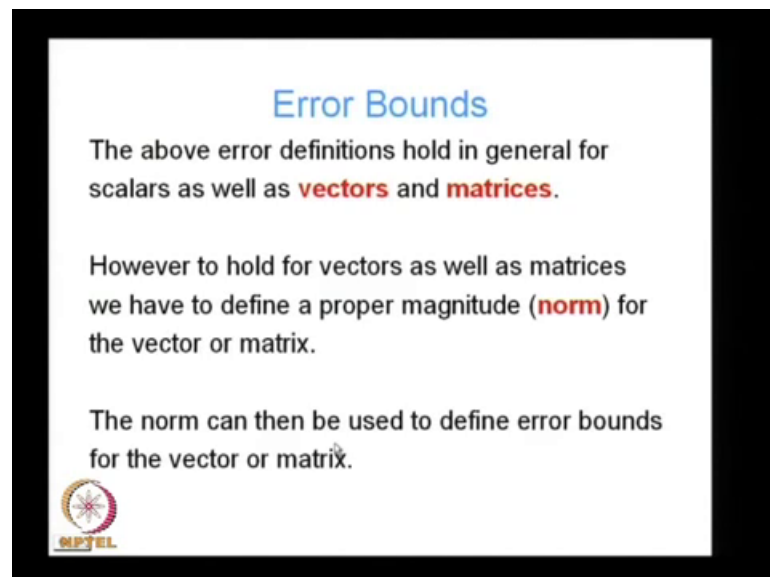

$$|\tilde{a} - a|$$

A bound on the relative error is a bound on

$$\left| \frac{\tilde{a} - a}{a} \right|$$

A bound on the magnitude of the error is known as an error bound. Thus a bound on the absolute error is a bound on a tilde minus a, it is a bound on the absolute value of a tilde minus a, a bound on the relative error on the other hand is a bound on the absolute value of a tilde minus a divided by a.

(Refer Slide Time: 20:52)

Error Bounds

The above error definitions hold in general for scalars as well as **vectors** and **matrices**.

However to hold for vectors as well as matrices we have to define a proper magnitude (**norm**) for the vector or matrix.

The norm can then be used to define error bounds for the vector or matrix.

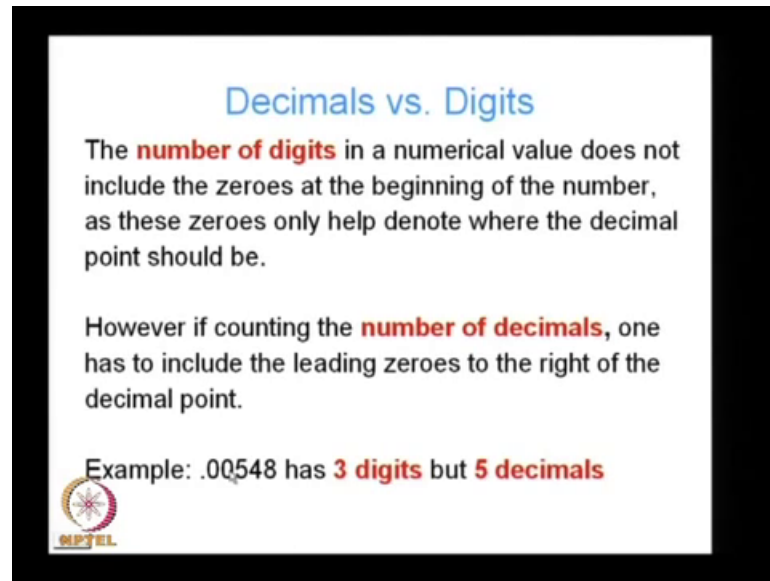

The above error definitions hold in general for scalars as well as vectors and matrices. In our definition of absolute error and relative error we looked at scalars a is assume to be a scalar, but we now, saying that a can as well b a vector or a matrix provided we can

calculate a value for the magnitude of the vector or the matrix or we can calculate a value of the norm of the vector or the matrix.

Once we can calculate the value of the magnitude of the norm of the vector or matrix we can use that norm to define error bounds for the vector or the matrix.

(Refer Slide Time: 21:46)

Decimals vs. Digits

The **number of digits** in a numerical value does not include the zeroes at the beginning of the number, as these zeroes only help denote where the decimal point should be.

However if counting the **number of decimals**, one has to include the leading zeroes to the right of the decimal point.

Example: .00548 has **3 digits** but **5 decimals**

That was about errors about relative errors an absolute errors, next we how do we measure errors how do we decide how much is the error to decide that, we have to talk about the measures of accuracy in order to talk about to measure is of accuracy we want to talk about decimals the errors interns of decimals an errors interns of digits, the number of digits in a numerical value does not include the zeroes at the beginning of the number as these zeroes only help denote where the decimal point should be.

However, if we are counting the number of decimals one has to include the leading 0es to the right of the decimal point. These becomes clear if we considered an examples for instance the number 0.00548 has only three digits because, we ignore the two zeroes which occur at the beginning of the number however, it has got five decimals since the number of decimals include the leading zeroes to the right of the decimal point.

(Refer Slide Time: 23:00)

Magnitude of error

If the magnitude of the error (whether absolute or relative) in the numerical result does not exceed

$$\frac{1}{2} \times 10^{-t}$$

then the numerical approximation, say, \tilde{a} , can be assured to have **t correct decimals**.

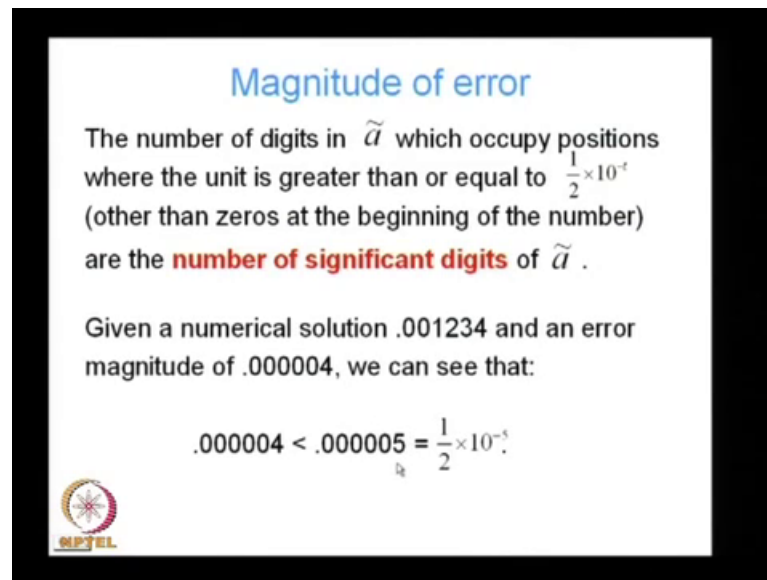

Example: if the absolute magnitude of error does not exceed say $\frac{1}{2} \times 10^{-3}$ or .0005 then we are certain that the numerical approximation has **3 correct decimals**.

 MPTEL

If the magnitude of the error whether it be the absolute error or relative error in the numerical result does not exceed half times 10 to the power minus t, then we say by definition that the numerical approximation, a tilde has t correct decimals. That is if the error is lesser than 0.5 times 10 to the power minus t the error is set to have t correct decimals.

Again we considered an example if the absolute magnitude of error does not exceeds a half into 10 to the power minus three or 0.0005 then we are certain that the numerical approximation has three correct decimals this is evident because, the error is only appearing in the 4th decimal place and the a magnitude of the error is less than 0.0005. So, the first three decimals in a tilde in the numerical approximation must be correct, so the number has three correct decimals a numerical approximation has three correct decimals.

(Refer Slide Time: 24:28)

Magnitude of error

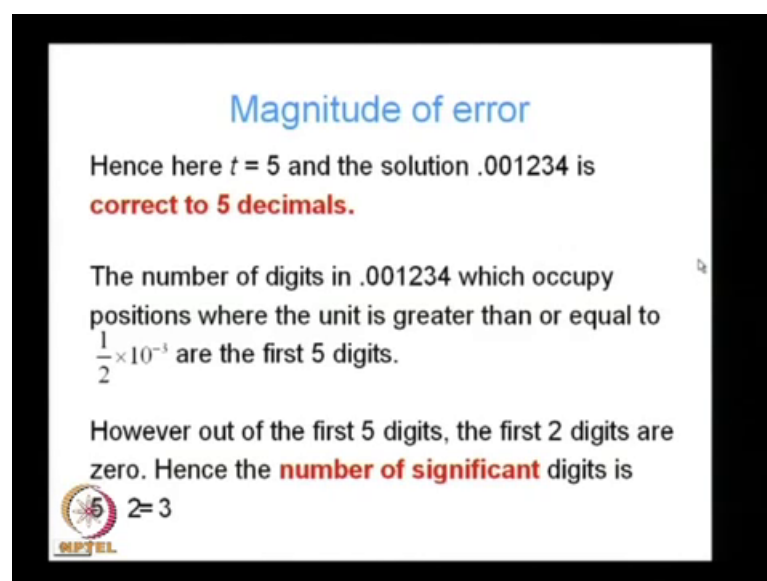

The number of digits in \tilde{a} which occupy positions where the unit is greater than or equal to $\frac{1}{2} \times 10^{-t}$ (other than zeros at the beginning of the number) are the **number of significant digits** of \tilde{a} .

Given a numerical solution .001234 and an error magnitude of .000004, we can see that:

$$.000004 < .000005 = \frac{1}{2} \times 10^{-5}$$

The number of digits in a tilde which occupy positions where the unit is greater than or equal to, half into 10 to the power minus t of course, we ignore the zeroes at the beginning of the number other number of significant digits of a tilde. Suppose, we have a numerical solution 0.001234 and we know that, the numerical solution has an error of magnitude 0.000004 we can see that 0.000004 is of course, less than 0.000005 which is equal to half times 10 to the power minus 5, thus we can see there are error is in this 6 decimal place because the error is in the 6 decimal place.

(Refer Slide Time: 25:33)

Magnitude of error

Hence here $t = 5$ and the solution .001234 is **correct to 5 decimals**.

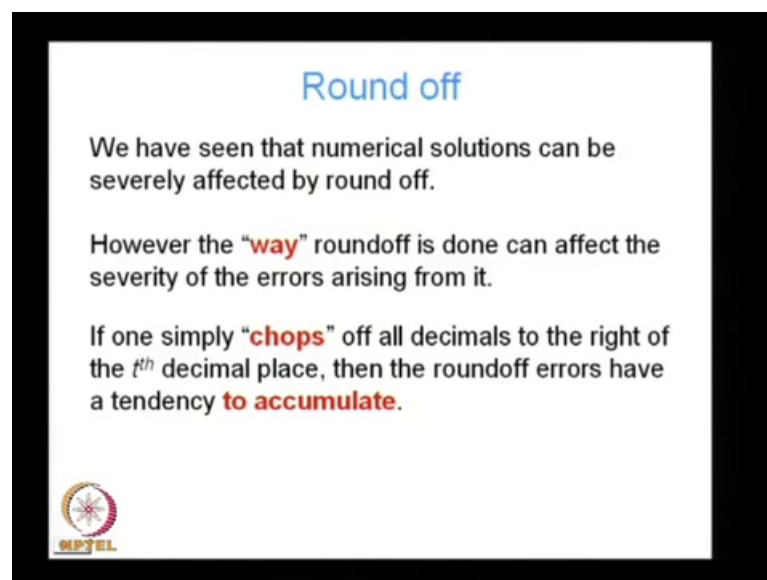

The number of digits in .001234 which occupy positions where the unit is greater than or equal to $\frac{1}{2} \times 10^{-5}$ are the first 5 digits.

However out of the first 5 digits, the first 2 digits are zero. Hence the **number of significant digits** is

$$5 - 2 = 3$$

So, we can see that we have five correct decimals, that is here in this solution t is equal to five and the solution 0.001234 is correct to 5 decimals the number of digits in 0.001234, which occupy positions where the unit is greater than or equal to, half in to 10 to the power minus three are the first five digits this should actually be half in to 10 to the power minus five I apologized for the type, but the number of digits 0.001234 which occupy positions where the unit is greater than or equal to half in to 10 to power minus 5 are the first five digits. However, out of the first five digits the first 2 digits are 0 the first 2 digits are 0 hence the number of significant digits is five minus 2 is equal to three. So, we have three significant digits in our numerical solution

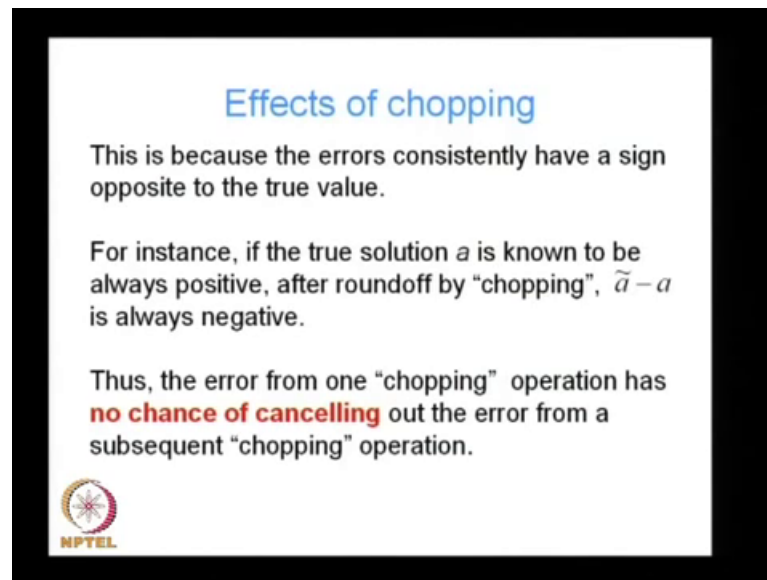

(Refer Slide Time: 26:53)

We have seen previously that numerical solutions are severely affected by round off. However, the way we do the round off is critical and can affect the severity of the errors arising from round off if, one simply chops off all the decimals to the right of the t^{th} decimal place then the round off errors have a tendency to accumulate, suppose our solution our number has s digits.

but if we suppose if we chop it off after the t^{th} decimal place then we all the numbers which followed the t^{th} decimal place get removed from a numerical solution, but if we do this chopping arbitrarily if we do this round off arbitrarily then we will see that these round off errors have a tendency to accumulate.

(Refer Slide Time: 28:00)

Effects of chopping

This is because the errors consistently have a sign opposite to the true value.

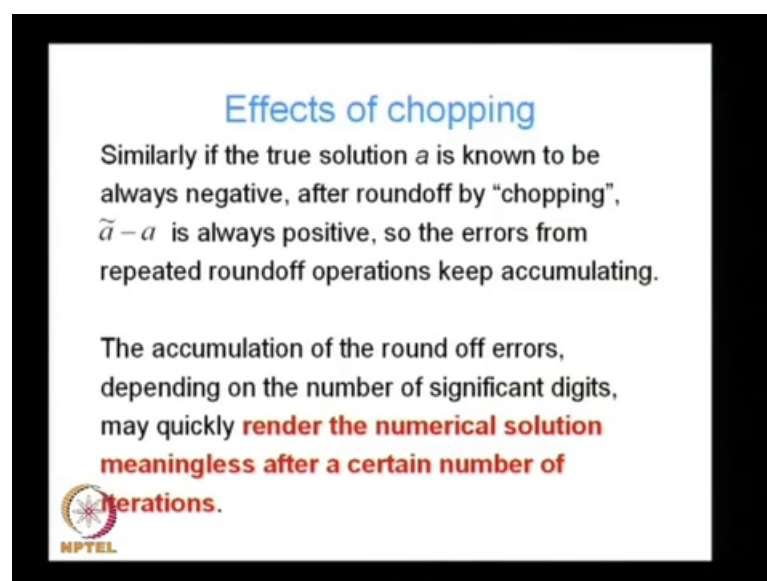

For instance, if the true solution a is known to be always positive, after roundoff by "chopping", $\tilde{a} - a$ is always negative.

Thus, the error from one "chopping" operation has **no chance of cancelling** out the error from a subsequent "chopping" operation.

This is because the errors consistently have a sign opposite to the true value, for instance if the true solution a is known to be always positive, after round off by chopping a tilde minus a is always going to be negative. Because after chopping a tilde has to be less than a because we have got rid of the additional digits which follow the t th digits, so a tilde has got to be less than a and a tilde minus a will always be negative, thus the error from chop one chopping operation has no chance of canceling out the error from a subsequent chopping operation.

(Refer Slide Time: 28:46)

Effects of chopping

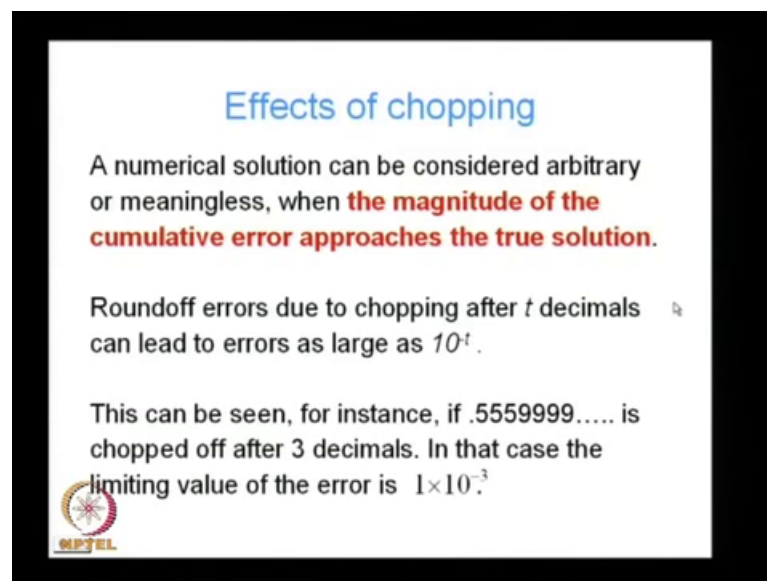

Similarly if the true solution a is known to be always negative, after roundoff by "chopping", $\tilde{a} - a$ is always positive, so the errors from repeated roundoff operations keep accumulating.

The accumulation of the round off errors, depending on the number of significant digits, may quickly **render the numerical solution meaningless after a certain number of iterations.**

Similarly, if the true solution a is known to be always negative, after round off by chopping \tilde{a} is always going to be positive because, \tilde{a} is going to be less negative than a , so \tilde{a} is going to be always positive, so the errors from repeated round off operations will keep accumulating. The accumulation of the round off errors depending on the number of significant digits may quickly render the numerical solution meaningless after a certain number of iterations.

(Refer Slide Time: 29:35)

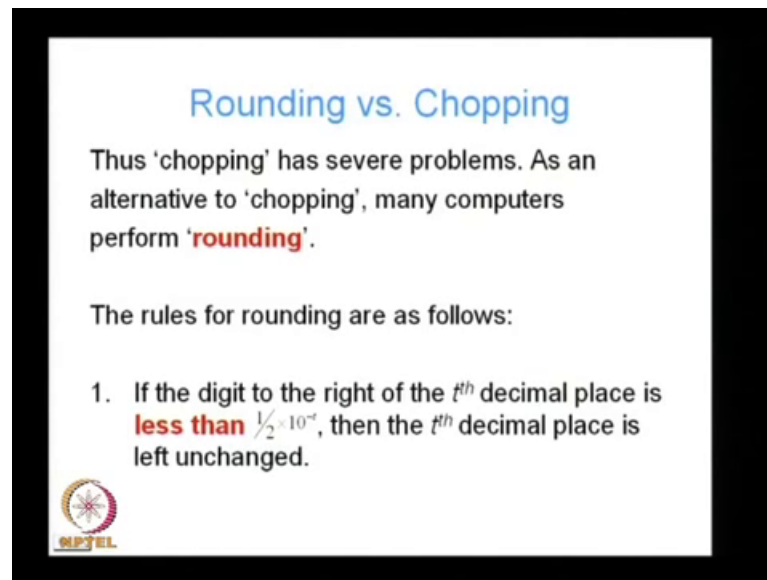

The slide is titled "Effects of chopping" in blue text. It contains three main paragraphs of text. The first paragraph states that a numerical solution is arbitrary or meaningless when the magnitude of the cumulative error approaches the true solution. The second paragraph explains that roundoff errors from chopping after t decimals can lead to errors as large as 10^{-t} . The third paragraph provides an example: chopping the number 0.5559999... after 3 decimals results in a limiting error of 1×10^{-3} . In the bottom left corner, there is a small circular logo with the text "NPTEL" below it.

A numerical solution can be considered arbitrary or meaningless, when the magnitude of the cumulative error approaches the true solution, round off errors due to chopping after t decimals can lead to errors as large as 10^{-t} . This can be seen for instance if we consider the number 0.5559999 up to infinity, then if we chop this number after three decimals that is we store only 0.555 in our computer.

In that case the error has error is of magnitude 0.00099999 up to infinity and the limiting value of the error, we can see is one in to 10^{-3} , that is round off errors to due to chopping after three decimals can lead to errors as large as 10^{-3} .

(Refer Slide Time: 30:40)

Rounding vs. Chopping

Thus 'chopping' has severe problems. As an alternative to 'chopping', many computers perform '**rounding**'.

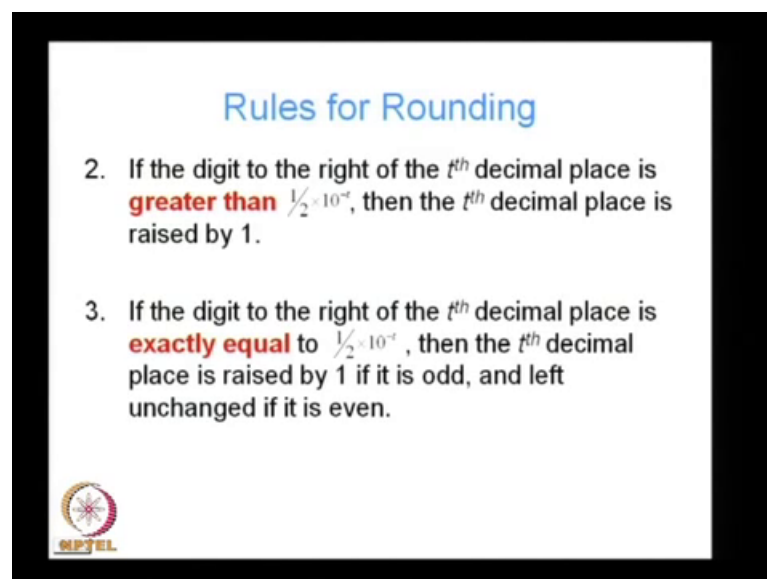

The rules for rounding are as follows:

1. If the digit to the right of the t^{th} decimal place is **less than** $\frac{1}{2} \times 10^{-t}$, then the t^{th} decimal place is left unchanged.

Thus chopping is seen to have severe problems as an alternative to chopping many computers perform what is known as rounding. The rules for rounding are as follows there are three rules, the first rules says if the digit to the right of the t^{th} decimal place is less than half in to 10 to the power minus t then the t^{th} decimal place is left unchanged, for instance if we are considering t equal to three if the digit to the right of the third decimal place is less than 0.0005 that is half in-to 10 to the power minus three which is 0.0005 then the third decimal place is going to be left unchanged.

(Refer Slide Time: 31:36)

Rules for Rounding

2. If the digit to the right of the t^{th} decimal place is **greater than** $\frac{1}{2} \times 10^{-t}$, then the t^{th} decimal place is raised by 1.
3. If the digit to the right of the t^{th} decimal place is **exactly equal** to $\frac{1}{2} \times 10^{-t}$, then the t^{th} decimal place is raised by 1 if it is odd, and left unchanged if it is even.

If the digit to the right of the t th decimal place on the other hand is greater than half in to 10 to the power minus t , then the t th decimal place is raised by one, for instance in our example if our number is 0.3254 then the first rule would apply the first rule would tell me I have to approximate 0.3 to 54 as 0.3 to 5. Because, the digit to the right of the t th decimal place is less than 5 in to 10 the power minus 4 however, if my number is for instance 0.3256, then we are going to we are going to store 0.3 to 56 as 0.3 to 0.6 because, the number to the right of the t th.

In this case the third decimal place is 0.0006 which is greater than 0.0005 which is half in to 10 to the power minus 3 then because of, that we have raised that t th decimal place we have change 0.325 to 0.326, if the digit to the right of the t th decimal place is exactly equal to half in to 10 to the power minus t then the t th decimal place is raised by one if it is odd and left unchanged if it is even. So, these are our three rules for rounding.

We can we will see that these rules result in lower error magnitudes for instance, let us consider rule three the rule three says that if the let us go back and look at rule three again which says that if the digit to the right of the t th decimal place is exactly equal to half in to the 10 to the power minus t . Then the t th decimal place is raised by one if it is odd and left unchanged if it is even.

(Refer Slide Time: 33:45)

Rules for rounding

Since the probability of the t^{th} decimal place being odd or even is equal (each probability being equal to half), if rule 3 is followed the resulting error will be positive or negative equally often.

The errors will thus **tend to cancel off and not accumulate.**

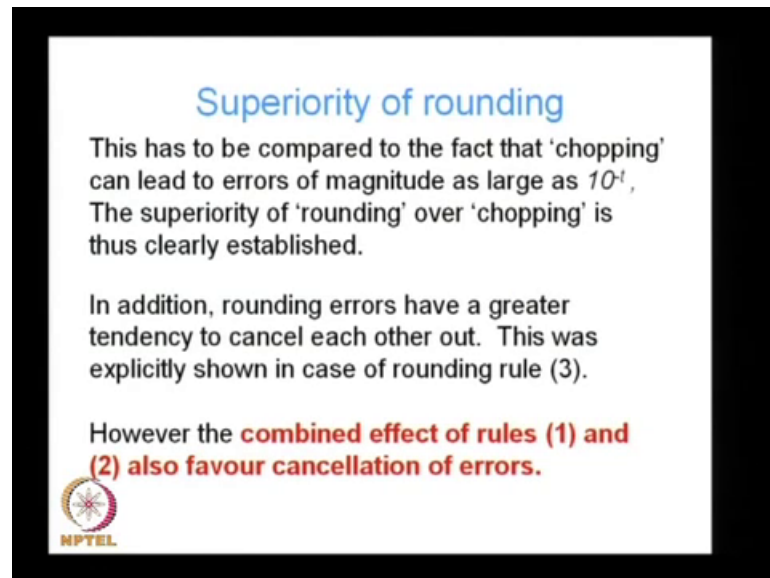

If the above rules are followed, then the error due to rounding off lies in the interval $\left[-\frac{1}{2} \cdot 10^{-t}, \frac{1}{2} \cdot 10^{-t}\right]$

 NPTEL

Since the probability of the t th decimal place being odd or even is equal each probability being equal to half, if rule three is followed the resulting error will be positive or

negative equally of 10^{-t} because, the possibility of the t th decimal place being odd or even is equal. So, the resulting error we get is also going to be positive or negative equally of 10^{-t} the errors will thus tend to cancel off and not accumulate, if the above rules are followed then the error due to rounding off lies in the interval $-\frac{1}{2} \times 10^{-t}$ to $\frac{1}{2} \times 10^{-t}$.

(Refer Slide Time: 34:39)

Superiority of rounding

This has to be compared to the fact that 'chopping' can lead to errors of magnitude as large as 10^{-t} . The superiority of 'rounding' over 'chopping' is thus clearly established.

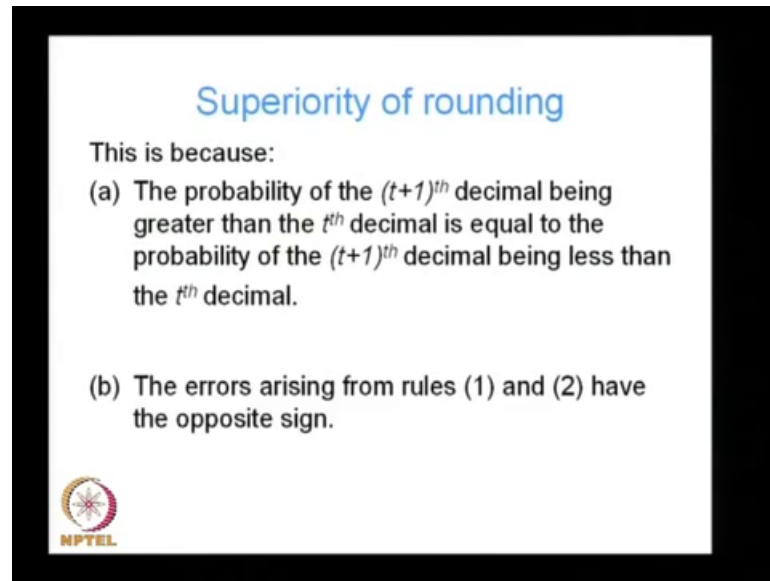

In addition, rounding errors have a greater tendency to cancel each other out. This was explicitly shown in case of rounding rule (3).

However the **combined effect of rules (1) and (2) also favour cancellation of errors.**

This is to be compared with the fact that if we do chopping instead of using around of algorithm which we just described we can get errors as large as 10^{-t} , instead of $\frac{1}{2} \times 10^{-t}$. Now, are errors lie in the range $-\frac{1}{2} \times 10^{-t}$ to $\frac{1}{2} \times 10^{-t}$, the superiority of rounding over chopping is thus clearly established in addition rounding errors have a greater tendency to cancel each other out. We should this explicitly in case of rounding rule three however, the combined effect of rules one and 2 also favor the cancellation of errors.

(Refer Slide Time: 35:29)

Superiority of rounding

This is because:

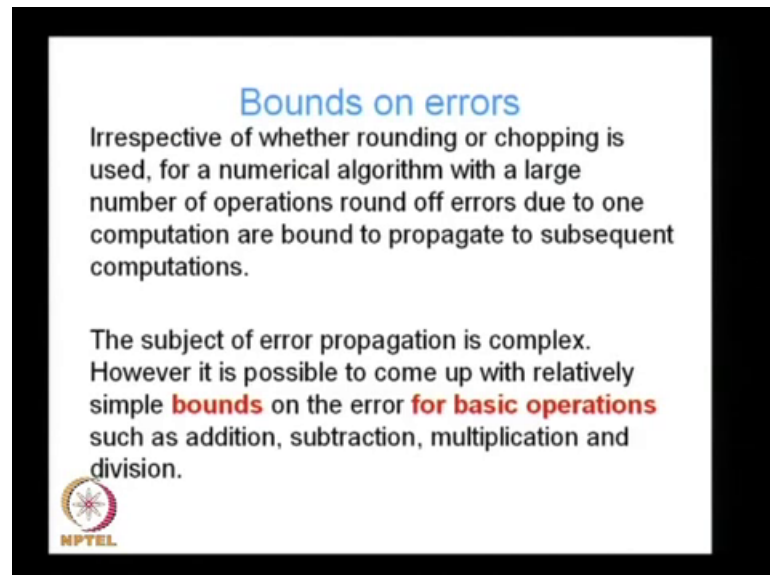

- (a) The probability of the $(t+1)^{th}$ decimal being greater than the t^{th} decimal is equal to the probability of the $(t+1)^{th}$ decimal being less than the t^{th} decimal.

- (b) The errors arising from rules (1) and (2) have the opposite sign.

This is because, the probability of the $t + 1$ th decimal being greater than the t th decimal is equal to the probability of the $t + 1$ th decimal being less than the t th decimal. The errors arising from rules one and 2 therefore, have opposite signs and therefore, have a tendency to cancel each other out.

(Refer Slide Time: 36:00)

Bounds on errors

Irrespective of whether rounding or chopping is used, for a numerical algorithm with a large number of operations round off errors due to one computation are bound to propagate to subsequent computations.

The subject of error propagation is complex. However it is possible to come up with relatively simple **bounds** on the error **for basic operations** such as addition, subtraction, multiplication and division.

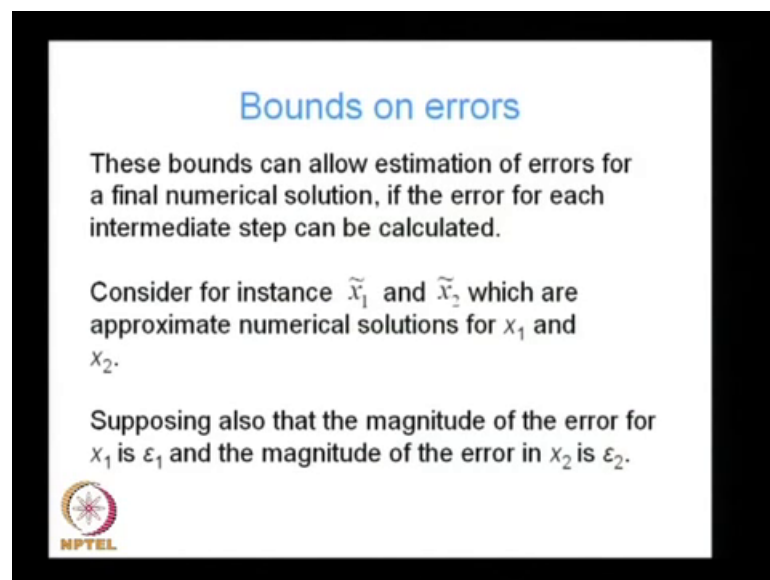

However, irrespective of whether rounding or chopping is used, for a numerical algorithm with a large number of operations round off errors due to one computation are bound to propagate to subsequent computations. The errors in one computation are going

to affect the results of the subsequent computation this is known as propagation of errors or error propagation the subject of error propagation is complex

However, it is possible to come up with relatively simple bounds on the error for basic operations such as addition subtraction multiplication and division. The idea being that if we can come up with simple bounds for the basic operations and since all numerical methods, are basically a combination of the simple operations of addition subtraction multiplication and division. if we know the errors due to each of these individual operations we can come up with an error for the entire numerical algorithm.

(Refer Slide Time: 37:35)

Bounds on errors

These bounds can allow estimation of errors for a final numerical solution, if the error for each intermediate step can be calculated.

Consider for instance \tilde{x}_1 and \tilde{x}_2 which are approximate numerical solutions for x_1 and x_2 .

Supposing also that the magnitude of the error for x_1 is ϵ_1 and the magnitude of the error in x_2 is ϵ_2 .

So, if we can again going back if we can bound these errors for the simple operations we can establish bounds for our final numerical solution, in case we compute the error for each intermediate step if we compute the error for each intermediate step and we keep adding we keep track of those errors. If we do some book keeping and if keep track of the those errors then we can get the final error in our numerical solution consider for instance x_1 tilde and x_2 tilde which are approximate numerical solutions for x_1 and x_2 . Supposing also that the magnitude of the error for x_1 is epsilon 1 and the magnitude of the error in x_2 is epsilon 2. This we know that the magnitude of the error in x_1 in is in epsilon 1 and the magnitude of the error in x_2 is epsilon 2 now, suppose knowing those two values knowing the magnitudes of the error in x_1 and x_2 .

(Refer Slide Time: 38:51)

Bounds on Addition & Subtraction

Then we can write:

$$x_1 = \tilde{x}_1 \pm \varepsilon_1, \quad x_2 = \tilde{x}_2 \pm \varepsilon_2$$

Hence the smallest possible value for x_1

$$x_1 = \tilde{x}_1 - \varepsilon_1$$

and the largest possible value for x_1

$$x_1 = \tilde{x}_1 + \varepsilon_1$$

We can write x_1 is equal to \tilde{x}_1 plus minus epsilon 1 and x_2 is equal to, \tilde{x}_2 plus minus epsilon 2 that is x_1 can be as low as \tilde{x}_1 minus epsilon 1 and can be as high as \tilde{x}_1 plus epsilon 1 similarly, x_2 can be as low as \tilde{x}_2 minus epsilon 2 and can be as high as \tilde{x}_2 plus epsilon 2. Hence the smallest possible value for x_1 is equal to \tilde{x}_1 minus epsilon 1 and the largest possible value for x_1 is equal to \tilde{x}_1 plus epsilon 1.

(Refer Slide Time: 39:58)

Bounds on Addition & Subtraction

Similarly the smallest possible value for x_2

$$x_2 = \tilde{x}_2 - \varepsilon_2$$

while the largest possible value for x_2

$$x_2 = \tilde{x}_2 + \varepsilon_2$$

Since $x_1 - x_2$ cannot be greater than the largest value of x_1 minus the smallest value of x_2 , we can write:

$$x_1 - x_2 \leq \tilde{x}_1 + \varepsilon_1 - (\tilde{x}_2 - \varepsilon_2) \dots \dots \dots (1)$$

Similarly, the smallest possible value for x_2 is also $\tilde{x}_2 - \epsilon_2$, where ϵ_2 recall is the error in x_2 and the largest possible value for x_2 is $\tilde{x}_2 + \epsilon_2$. Since $x_1 - x_2$ cannot be greater than the largest value of x_1 minus the smallest value of x_2 the magnitude of $x_1 - x_2$ cannot exceed the largest value of x_1 minus the smallest value of x_2 . We can write $x_1 - x_2$ is bounded on the right that is bounded has an upper bound $\tilde{x}_1 + \epsilon_1 - \tilde{x}_2 - \epsilon_2$ sorry this should not be ϵ_1 it is actually ϵ_1 , so $\tilde{x}_1 + \epsilon_1 - \tilde{x}_2 - \epsilon_2$.

(Refer Slide Time: 41:17)

Bounds on Addition & Subtraction

Using a similar argument, it can be shown that:

$$(\tilde{x}_1 + \tilde{x}_2) - (\epsilon_1 + \epsilon_2) \leq x_1 + x_2 \leq (\tilde{x}_1 + \tilde{x}_2) + (\epsilon_1 + \epsilon_2) \dots \dots \dots (4)$$

Combining (3) and (4) we get:

$$\|(x_1 - x_2) - (\tilde{x}_1 - \tilde{x}_2)\| \leq \epsilon_1 + \epsilon_2$$

$$\|(x_1 + x_2) - (\tilde{x}_1 + \tilde{x}_2)\| \leq \epsilon_1 + \epsilon_2$$

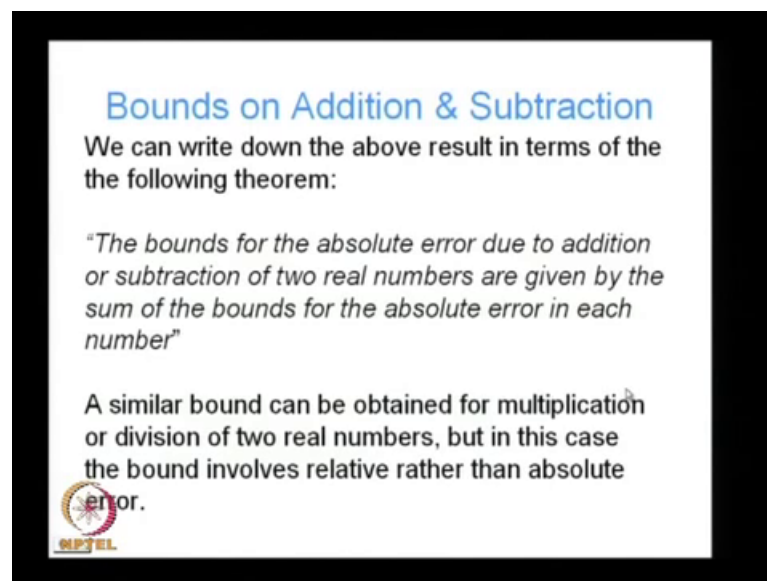

Similarly, since $x_1 - x_2$ cannot be less than the smallest value of x_1 minus the largest values of x_2 , we can write $\tilde{x}_1 - \epsilon_1 - \tilde{x}_2 + \epsilon_2$ must be lesser than or equal to $x_1 - x_2$ or $x_1 - x_2$ is bounded from below bounded. On the left by $\tilde{x}_1 - \epsilon_1 - \tilde{x}_2 + \epsilon_2$ because, $\tilde{x}_1 - \epsilon_1$ is the smallest value of x_1 smallest possible value of x_1 and $\tilde{x}_2 + \epsilon_2$ is the largest possible value of x_2 .

Combining equations 1 and 2 combining this equation with this equation we can get a bound on $x_1 - x_2$ which gives me a lower bound as well as an upper bound which tells me $x_1 - x_2$ is bounded from below by $\tilde{x}_1 - \tilde{x}_2 - \epsilon_1 + \epsilon_2$, while it is bounded from above by $\tilde{x}_1 - \tilde{x}_2 + \epsilon_1 - \epsilon_2$ using a similar argument now, instead of considering subtraction,

which we considered previously instead of considering x_1 minus x_2 , if we try to get bounds for addition that is we try to get bounds on x_1 plus x_2 . By using a very similarly, argument we can show that x_1 plus x_2 is also bounded from above and below by this by x_1 tilde plus x_2 tilde minus epsilon 1 plus epsilon 2 from below and x_1 tilde plus x_2 tilde plus epsilon 1 plus epsilon 2 from above.

Combining bounds 3 and 4 we get norm of that is absolute value of x_1 minus x_2 minus x_1 tilde minus x_2 tilde, must always be less than epsilon 1 plus epsilon 2 and x_1 the bound on x_1 plus x_2 minus x_1 tilde plus x_2 tilde is always lesser than or equal to epsilon 1 plus epsilon 2, thus the error due to subtraction is bounded by, epsilon plus epsilon 1 plus epsilon 2. Similarly the error due to addition is also bounded by epsilon one plus epsilon 2.

(Refer Slide Time: 42:48)

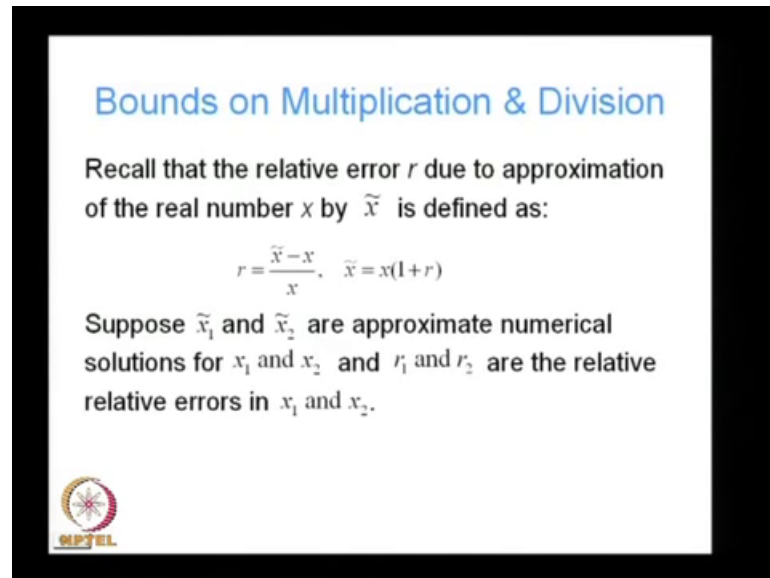

We can write down the above result in terms of the following theorem, which states that the bounds for the absolute error due to addition or subtraction of 2 real numbers in our case x_1 and x_2 are given by the sum of the bounds for the absolute error in each number, the sum of the bounds on the on the absolute error in each number which is epsilon 1 which is the absolute error in x_1 and epsilon 2 which is the absolute error in x_2 .

A similar bound can be obtained for multiplication or division of 2 real numbers, but in this case the bound involves relative rather than absolute error. Till now, we have been

considering absolute errors in evaluating our bounds, but in order to obtain bounds for multiplication or division of two real numbers we have to consider relative rather than absolute error.

(Refer Slide Time: 45:32)

Bounds on Multiplication & Division

Recall that the relative error r due to approximation of the real number x by \tilde{x} is defined as:

$$r = \frac{\tilde{x} - x}{x}, \quad \tilde{x} = x(1+r)$$

Suppose \tilde{x}_1 and \tilde{x}_2 are approximate numerical solutions for x_1 and x_2 and r_1 and r_2 are the relative relative errors in x_1 and x_2 .

Again recall from our definition of relative error r due to the approximation of a real number x by \tilde{x} we can define, the relative error as r is equal to \tilde{x} minus x divided by x or \tilde{x} is equal to x times of one plus r . Suppose \tilde{x}_1 and \tilde{x}_2 are approximate numerical solutions for x_1 and x_2 and r_1 and r_2 are the relative errors in x_1 and x_2 . In that case we can write the product \tilde{x}_1 times \tilde{x}_2 as x_1 times $1 + r_1$ recall \tilde{x} is equal to x plus r . So, \tilde{x}_1 is equal to x_1 times one plus r_1 times \tilde{x}_2 which is x_2 times one plus r_2 which gathering terms.

(Refer Slide Time: 46:16)

Bounds on Multiplication & Division

Then we can write:

$$\tilde{x}_1 \tilde{x}_2 = x_1(1+r_1)x_2(1+r_2) = x_1x_2(1+r_1)(1+r_2)$$

Thus the relative error in x_1x_2 is:

$$(1+r_1)(1+r_2) - 1 = r_1 + r_2 + r_1r_2 \approx r_1 + r_2 \text{ if } |r_1| \ll 1, |r_2| \ll 1$$

Similarly the relative error in the quotient from:

$$\frac{\tilde{x}_1}{\tilde{x}_2} = \frac{x_1(1+r_1)}{x_2(1+r_2)}$$

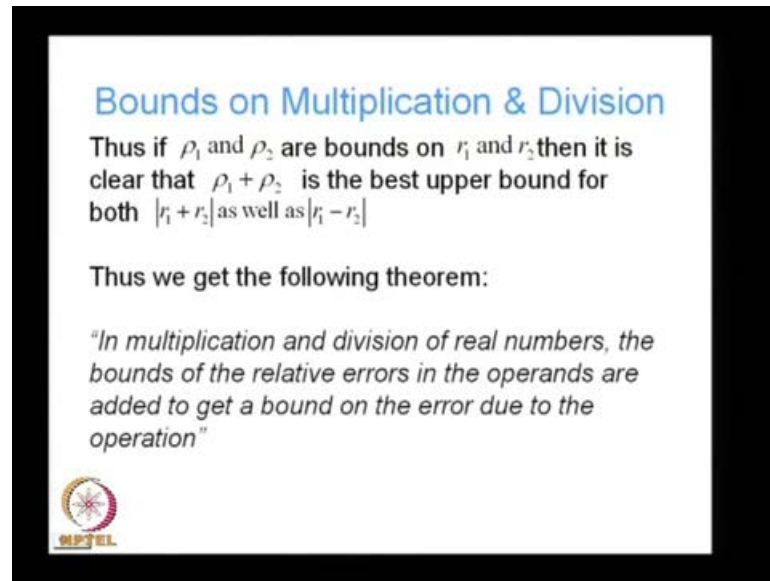

is found to be: $\frac{1+r_1}{1+r_2} - 1 \approx \frac{r_1 - r_2}{1+r_2} \approx r_1 - r_2 \text{ if } |r_1| \ll 1, |r_2| \ll 1$

We can write, x_1 times x_2 times $1 + r_1$ into $1 + r_2$, thus the relative error in x_1x_2 is given by again from our definition the relative error will be given by x_1 tilde times x_2 tilde minus x_1x_2 divided by x_1x_2 . So, if we take x_1 tilde x_2 tilde we subtract x_1x_2 from it we get x_1x_2 times $1 + r_1$ times $1 + r_2$ minus x_1x_2 dividing the whole thing by x_1x_2 , we get $1 + r_1$ times $1 + r_2$ minus 1 which is equal to $r_1 + r_2 + r_1r_2$.

Suppose r relative errors in x_1 and x_2 are the much smaller than one in that case we can write $r_1 + r_2 + r_1r_2$ to be approximately equal to $r_1 + r_2$. Similarly, the relative error in the quotient can be evaluated for instance, x_1 tilde by x_2 tilde which is the quotient of x_1 and x_2 in terms of it is numerical solutions x_1 tilde and x_2 tilde can be written as x_1 times $1 + r_1$ divided by x_2 times $1 + r_2$, the relative error in the quotient will then be equal to x_1 tilde divided by x_2 tilde minus x_1 by x_2 divided by x_1 by x_2 .

Which we if perform that operation we get $1 + r_1$ divided by $1 + r_2$ minus 1 which is approximately equal to $r_1 - r_2$ divided by $1 + r_2$, which is not approximately which is actually exactly equal to $r_1 - r_2$ divided by $1 + r_2$ and which is approximately equal to $r_1 - r_2$ if r_2 is much less than one.

(Refer Slide Time: 49:10)

Bounds on Multiplication & Division

Thus if ρ_1 and ρ_2 are bounds on r_1 and r_2 then it is clear that $\rho_1 + \rho_2$ is the best upper bound for both $|r_1 + r_2|$ as well as $|r_1 - r_2|$

Thus we get the following theorem:

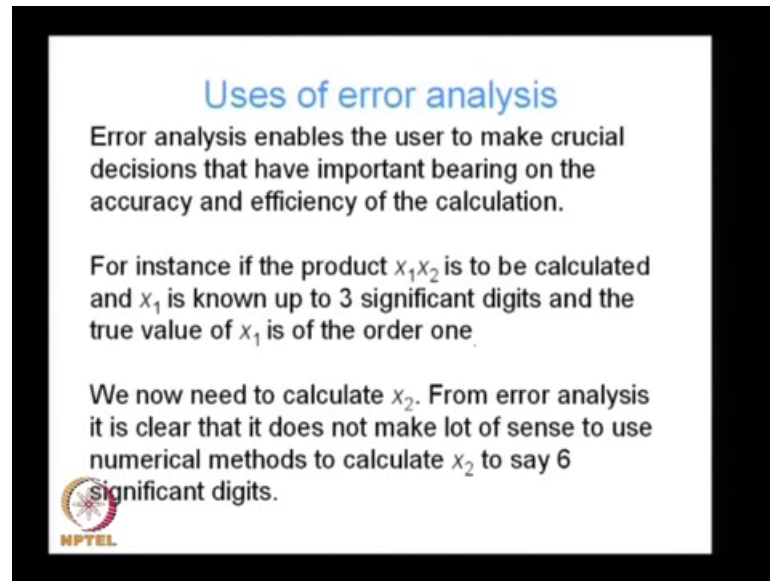

"In multiplication and division of real numbers, the bounds of the relative errors in the operands are added to get a bound on the error due to the operation"

Thus if ρ_1 and ρ_2 are bounds on the relative errors r_1 and r_2 then it is clear that $\rho_1 + \rho_2$ is the best upper bound for both $r_1 + r_2$ as well as $r_1 - r_2$. If we want to find bounds on $r_1 + r_2$ which is the relative error due to multiplication and $r_1 - r_2$ which is the relative error due to division we know that the relative error due to $r_1 + r_2$ is bounded by the sum of the errors in r_1 and r_2 ρ_1 and ρ_2 .

Thus if ρ_1 and ρ_2 are bounds on r_1 and r_2 then $\rho_1 + \rho_2$ is the best upper bound for both $r_1 + r_2$ as well as $r_1 - r_2$. From this we get the following theorem, which states that in multiplication and division of real numbers the bounds of the relative errors in the operations are added to get a bound on the error due to the operation, basically which tells me that the bound of the error due to multiplication division is bounded by the sum of the relative errors in x_1 and x_2 .

(Refer Slide Time: 50:50)

Uses of error analysis

Error analysis enables the user to make crucial decisions that have important bearing on the accuracy and efficiency of the calculation.

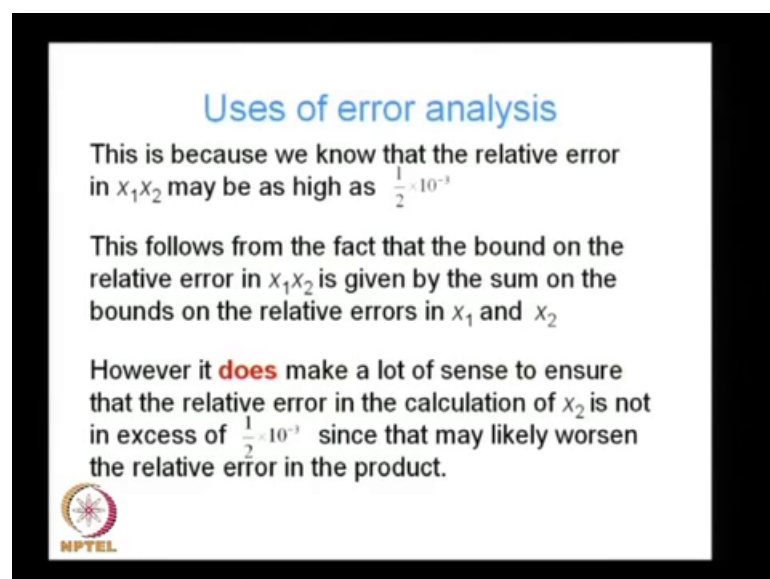

For instance if the product x_1x_2 is to be calculated and x_1 is known up to 3 significant digits and the true value of x_1 is of the order one.

We now need to calculate x_2 . From error analysis it is clear that it does not make lot of sense to use numerical methods to calculate x_2 to say 6 significant digits.

Error analysis enables the user to make crucial decisions that have important bearing on the accuracy and efficiency of the calculation. For instance if the product x_1x_2 is to be calculated and x_1 is known up to three significant digits and the true value of x_1 is of the order 1 and we have to decide to what degree of accuracy we need to calculate x_2 we already know the value of x_1 and we know that it is accurate up to three significant digits and then we have to calculate the value of x_2 to in order to minimize the error in the product x_1x_2 . We from error analysis it is clear to us that it does not make a lot of sense to use numerical methods to calculate x_2 to say six significant digits.

(Refer Slide Time: 51:51)

Uses of error analysis

This is because we know that the relative error in x_1x_2 may be as high as $\frac{1}{2} \times 10^{-3}$

This follows from the fact that the bound on the relative error in x_1x_2 is given by the sum on the bounds on the relative errors in x_1 and x_2

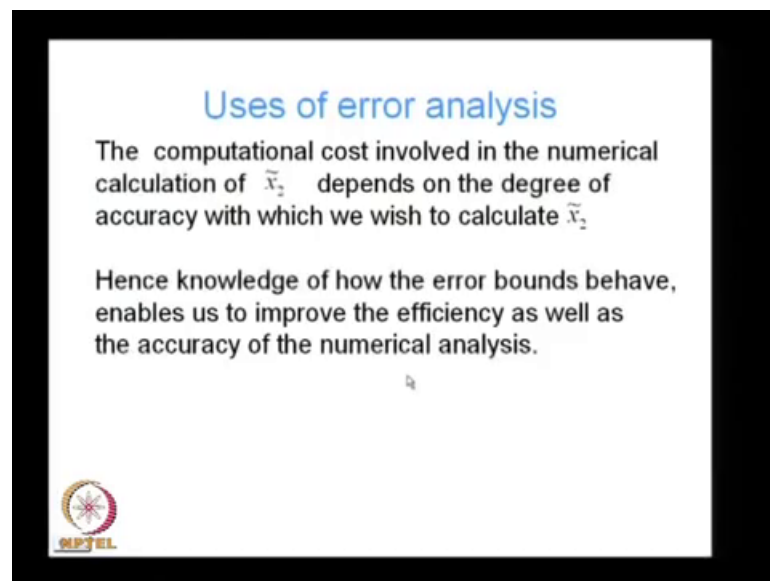

However it **does** make a lot of sense to ensure that the relative error in the calculation of x_2 is not in excess of $\frac{1}{2} \times 10^{-3}$ since that may likely worsen the relative error in the product.

Why is that this is because we know that the relative error in $x_1 \times x_2$ may be as high as half in to 10 to the power minus 3 because, our error in x_1 is because x_1 known only up to three significant digits. So, the error in x_1 is bounded by half in to 10 to the power minus 3 and since the error in the product is bounded by the sum of the errors in the operands themselves, in that case the error in $x_1 \times x_2$ can be as high as half in to 10 to the power minus 3.

This follows from the fact as we mentioned then the bound on the relative error in $x_1 \times x_2$ is given by the sum of the sum on the bounds on the relative errors in x_1 and x_2 . So, there is no sense in calculating x_2 to an accuracy greater than three significant digits. However it does make a lot of sense of ensure that the relative error in the calculation of x_2 is not in excess of half in to the 10 to the power minus 3 that is the error in x_2 should not be more than three significant digits since that is going to worsen the relative error in the product.

(Refer Slide Time: 53:21)

Since the computational cost involved in the numerical calculation of x_2 tilde depends on the degree of accuracy with which we wish to calculate x_2 tilde. Thus error using error analysis we can find out to what degree of accuracy we wish to calculate x_2 tilde this gives us important information important information which helps us improve the efficiency as well as the accuracy of our numerical analysis.

So, at the end of this lecture let us sum up, so we have looked at different types of errors and we have looked at absolute errors we have looked at relative errors, we have looked at how bounds on those errors. We have found out how we can bound errors absolute errors as well as relative errors and we have shown how we can use those bounds to find out the total error estimate for a numerical solution, by bounding individual operations such as addition, multiplication, subtract, addition, multiplication, subtraction and division. We can actually find bounds on the total numerical solution next time we are going to continue our discussion on error analysis and look at how knowing, if we know the errors on individual variables x_1 through x_n . And we can find out the error on y which is a function of individual variables x_1 through x_n .
