The Reversibility Markov Chains Contd...

(Refer Slide Time: 00:16)

Definition, a DTMC, this definition holds for finite as well as countable states maybe I should say DTMC with stationary distribution; π_i is said to be reversible, if P_{ij}^* derived above = P_{ji} for all i, j belongs to S , i.e is the same as saying $\pi_i P_{ij} = \pi_j P_{ji}$ for all i, j belongs to S . So, if $\pi_i P_{ij} = \pi_j P_{ji}$ for all i, j belongs to S then we will have $P_{ij}^* = P_{ji}$, which means that that transition probability from i to j in the forward chain is the same as the transition probability from i to j in the reverse chain for every i, j .

Such a Markov chain is said to be reversible. So, what this is saying is? If you look at a picture this is i , this is j so you have some this is the detail balance, this is P_{ij} , P_{ji} . So, for any 2 pairs of states the rate of transition from i to j is the same as the rate of transition from j to i for any 2 i either it could be i to k , j to k , k to l any 2 pairs of states in the Markov chain, this should hold. This is again the local balance or sometimes known as detailed balance, local balance equations or detailed balance equations.

So, reversibility is basically local balance holding for any 2 pairs of states, it is defined in terms of local balance, excellent. So, that is what reversibility is. So, if $\pi_j P_{ji} = \pi_i P_{ij}$, then we know that the forward running Markov chain and the reverse running Markov chain are statistically completely indistinguishable. So, if somebody shows you a videotape of transitions going forward let us say i go from state i, j, k in the forward chain. And I run it in reverse the statistical properties will be identical.

So, you will not be able to tell whether the tape is running forward or tape is running backward for the reversible Markov chain, in general you can. So, in general if you take some Markov chain the reverse transition probabilities will be like P_{ij}^* which are derived here. It so happens that for reversible Markov chains by definition $P_{ij}^* = P_{ij}$ and you will not be able to tell by looking at the statistics of transitions, you will not be able to tell whether the time is running in this direction or whether it is running in this direction.

(Refer Slide Time: 03:46)

The slide contains the following handwritten text:

Thm All birth-death chains with a stationary distribution are reversible.

Thm Suppose that an irreducible DTMC has T-pairs P_{ij} . Suppose $\{\pi_i, i \in S\}$ are a set of the numbers summing to 1, satisfying local balance

$$\pi_i P_{ij} = \pi_j P_{ji} \quad \forall i, j \in S.$$

Then

- (i) $\{\pi_i, i \in S\}$ is the stationary distribution of the DTMC
- (ii) The DTMC is recurrent & reversible.

Global balance!

$$\sum_{j \in S} \pi_j P_{ji} = \sum_{j \in S} \pi_i P_{ij} \Rightarrow \pi_i = \sum_{j \in S} \pi_j P_{ji} \quad \forall i \in S$$

\Rightarrow DTMC is recurrent

Now clearly this local balance equation is satisfied by Birth-Death chains. So, we can straightaway write down all Birth-Death chains with a stationary distribution or reversible. So, if just from our previous discussion we know that local balance is satisfied between any 2 pairs of states in Birth-Death chains. So, as long as the Birth-Death chain has a stationary distribution, has a π_i , which means that the Birth-Death chain is positive recurrent.

We are just saying that all positive recurrent Birth-Death chains are reversible. So, if you look at an evolution in the forward time of a Birth-Death chain or the reverse time you will not be able to tell the difference statistically. Now it looks like to establish, so how do you establish that a Markov chain is reversible or otherwise? You need to verify whether $\pi_i P_{ij} = \pi_j P_{ji}$ for every 2 parts of states i and j .

So, it looks like we are in an unhappy situation where you need to first figure out the stationary distribution π_i before you can even tell whether the Markov chain is reversible or not. It turns out that this is not necessary. There is a theorem that says that if you manage to guess some probability is π_i which satisfies local balance then these π_i 's are in fact your stationary probabilities, stationary distributions and that the underlying Markov chain is positive recurrent and reversible.

Suppose that an irreducible DTMC has transition probabilities P_{ij} and suppose π_i are a set of positive numbers summing to 1, satisfying local balance $\pi_i P_{ij} = \pi_j P_{ji}$ for all i, j in S . Then 3 things come for free, π_i are the, so π_i may be π_i is the stationary distribution of the DTMC, the DTMC is positive recurrent and reversible. So, this theorem is saying that see π_i you somehow find some π_i 's which sum to 1, satisfying local balance.

So, you are given P_{ij} the transition probabilities and you somehow managed to guess these π_i 's which are a probability distribution, such that local balance is satisfied between any 2 pairs of states. So, you do not know this is what these π_i 's are, you just manage to guess some numbers which sum to 1 and satisfying local balance. Then what happens is? This π_i are in fact the stationary distribution of the Markov chain, this π_i 's are unique and this is the stationary distribution.

And then the Markov chain is positive recurrent and reversible, so you get all of this for free. So, if you somehow manage to guess these π_i 's by looking at the structure of your chain or looking at your P_{ij} 's then you immediately get reversibility and you have automatically found out the

stationary distribution. So, proving this is actually easy, so since you have $\pi_i P_{ij} = \pi_j P_{ji}$. So, you know that this sum to 1, so you just sum this over j , this is true for all i .

So, I am just summing both sides over j , so if we look at the left hand side sum over, so π_i this is independent, this has no, nothing to do with the j at all. So, I can pull that out of summation and then I have some P_{ij} which is simply 1, sum over j P_{ij} is 1, so I get $\pi_i = \sum_j \pi_j P_{ji}$, now what is that? This is global balance. So, what have we shown? Local balance automatically implies global balance, because sum over $\pi_i = 1$, it is already given they sum to 1.

And we are looking at sum over j of the local balance equations I have $\pi_i = \sum_j \pi_j P_{ji}$. So, I am able to recover global balance from local balance, which means that local balance equations imply global balance. Converse is not true; if global balance is satisfied it is absolutely not the case that local balance should be satisfy, not at all the case. In that case if you satisfy global balance it does not imply your local balance, if it did then all Markov chains would be reversible, that is absolutely not true. But local balance always implies global balance.

And since we have these π_i 's which satisfy local balance and sum over $\pi_i = 1$, local balance implied global balance, so this π_i satisfies sum over $\pi_i = 1$ and global balance. And we already know that if π_i satisfy global balance, then these π_i 's are unique and the underlying Markov chain is positive recurrent. And these π_i 's are the unique stationary distribution of the Markov chain. So, this implies DTMC's positive recurrent and it also implies that π_i is the stationary distribution.

(Refer Slide Time: 11:47)

$\{\pi_i, i \in S\}$ Stationary distribution
 \Rightarrow Reversibility.

Suppose: (i) $p_{ij} > 0$ but $p_{ji} = 0$
 \Rightarrow Not reversible

(ii) $p_{ji} \cdot \pi_i \cdot p_{ij} \neq p_{ij} \cdot \pi_j \cdot p_{ji}$
 \Rightarrow Not reversible

So, the π_i that you manage to guess which satisfies local balance or normalization automatically becomes the stationary distribution of the Markov chain. Now that π_i have the interpretation of stationary distribution, you go back to local balance that implies reversibility. Now the local balance, so this implies reversibility also. Because now π_i 's are the interpretation of this stationary distribution and then this $\pi_i P_{ij} = \pi_j P_{ji}$ is satisfied for any 2 pairs of states and therefore the Markov chain is reversible.

So, this is a very nice elegant theorem which says that if you somehow manage to find these π_i 's which are normalized and satisfy local balance. Then these π_i 's are the steady state probabilities and that the underlying Markov chain is positive recurrent and reversible, this is a very useful theorem. There is one more related theorem which there is a theorem maybe I should not spend too much time on this.

So, if you find this theorem 6.5.3 in Gallager which says that if you find any π_i 's and some other P_{ji}^* with satisfy $P_{ji}^* = \pi_i P_{ij}$ over π_j . Then the Markov chain is such that it is positive recurrent π_i 's are the steady state probabilities and P_{ji}^* that you found are the transition probabilities of the reverse Markov chain, that also can be proven. But I think this theorem is much more useful although the next theorem I stated is more general, I think this is probably more useful.

So, this $\pi_i P_{ij} = \pi_j P_{ji}$ is quite useful. Now if you have a reverse, so there are some quick tests for reversibility that you can make. So, suppose $P_{ij} > 0$ but $P_{ji} = 0$, so you can go from i to j , so there is a k and all that. So, you can go from i to j but you cannot go from j to i , let us say there is a Markov chain like that. This Markov chain can never be reversible, why? Because $\pi_j P_{ji}$ will never be equal to $\pi_i P_{ij}$, intuitively the forward chain you will see transitions from i to j . But in the reverse chain, you will never find transitions from i to j , you will only see transitions from j to i in the reverse chain.

Because in the forward chain you will have transitions like i, j, k and all that, but in the reverse chain you will never be able to find transitions from i to j , you will always find transition j to i . Because reverse chain transition from i to j would mean a forward transition from j to i and that is not possible because P_{ji} is 0. So, if you have a situation where P_{ij} is greater than 0 but P_{ji} is 0 then you straightaway know that the Markov chain is not reversible.

And similarly for example if it so happens that $P_{ij} P_{jk} P_{ki}$ is not equal to the opposite $P_{ji} P_{ik} P_{kj}$. Suppose this is the case, so what am I saying? So, this is i, j, k , so P_{ij} , so probability of going from j to i and then i to k and k to j . If you are multiplying all these probabilities if this product is not the same as $P_{jk} P_{ki} P_{ij}$. If this product on the left is not equal to product on the right, then this chain can never be reversible.

Because the probability of going from i to j to k is different from the probability of going, so this probability in going the cycle in one direction is different from going in the other direction. So, the forward statistics or reverse statistic will not be the same in which case you can tell the difference, so the Markov chain cannot be reversible.

(Refer Slide Time: 17:24)

Indeed for a reversible chain,

$$\pi_i = \frac{\pi_j P_{ji}}{P_{ij}} = \frac{\pi_k P_{ki}}{P_{ik}} \Rightarrow \pi_j P_{ji} P_{ik} = \pi_k P_{ki} P_{ij}$$

dividing,

$$\pi_j P_{ji} P_{jk} = \pi_k P_{kj} P_{ij} \quad \forall i, j, k \in S$$

Reversibility \Leftrightarrow Detailed Balance \Leftrightarrow Can a finite DTMC be reversible?

So, indeed if it were reversible you have that π_i should be equal to $\pi_j P_{ji}$ over P_{ij} , that is equal to if it were reversible it should satisfy $\pi_k P_{ki}$ over P_{ik} . This should be true if the chain were reversible this should be true which implies $\pi_j P_{ji} P_{ik} = \pi_k P_{ki} P_{ij}$, so this should be true. And also we should have $\pi_j P_{jk} = \pi_k P_{kj}$. So, if you divide these 2 equations, so these 2 equations have to hold if the chain were reversible. And if you divide this equation you will get $P_{ji} P_{ik} P_{kj} = P_{jk} P_{ki} P_{ij}$, so what this is saying is that?

(Refer Slide Time: 19:21)

\Rightarrow Not reversible

(ii) $P_{ji} \cdot P_{ik} \cdot P_{kj} \neq P_{jk} P_{ki} P_{ij}$

\Rightarrow Not reversible

Indeed for a reversible chain,

$$\pi_i = \frac{\pi_j P_{ji}}{P_{ij}} = \frac{\pi_k P_{ki}}{P_{ik}} \Rightarrow \pi_j P_{ji} P_{ik} = \pi_k P_{ki} P_{ij}$$

dividing

$$\pi_j P_{jk} = \pi_k P_{kj}$$

If you product the probability is going that way and the probability is going that way, they should be equal, this should be true for all i, j, k . Even if for 1 triple i, j, k if this is not true then the chain will not be reversible. Similarly you can show this for cycles of length 4 cycles of length 5,

for any cycle of length 4 you should have the probability of going in this way is equal to probability of going the other way.

Even if there is some cycle where the probability of going in this way is not equal going in the opposite way then the chain cannot be reversible. So, it is necessary what is surprising? So, for every cycle a reversibility would; so it is necessary that the product of probabilities this way should be equal to the product of probabilities in the opposite direction. But it turns out that it is also sufficient, if for every cycle if the product of probability is going one way is equal to the product of going the other way for every cycle.

Then you can show that the chain is in fact reversible that is a more non-trivial result. But it turns out that it is both necessary and sufficient, that is anyway just an aside. So, before I conclude this discussion, I want to talk about reversibility and periodicity. The question is, can a periodic DTMC be reversible? So far we discussed periodicity long ago, which means that returns to the same state happen only in multiples of it is certain d .

If that is the case then we say that the state is periodic with period d , where d is greater than 1. Now can a periodic DTMC be reversible? Remember, that for a periodic DTMC let us say of period d , I can subdivide the states into these classes, where all the transitions happen from S_0 to S_1 , S_1 to S_2 dot, dot, dot and then S_{d-1} to S_0 . You can always subdivide the states into these subclasses, where all the transitions go from S_0 to S_1 , S_1 to S_2 , S_2 to S_3 , S_{d-1} to S_0 , all transitions go this way. Now imagine what reversibility means? You cannot have a, see then it is not possible to go from S_0 to S_{d-1} , S_{d-1} to S_{d-2} and so on.

Because all transition only go this way, if I run the time in reverse all the transitions will go in the reverse direction and therefore the statistics will not be the same. So, in this picture it appears that a periodic Markov chain cannot be reversible except if $d = 2$, if d is $= 2$ what happens? You have only a partition of 2 that is S_0 , that is S_1 . So, all transitions go from S_0 to S_1 and S_1 to S_0 . So, you will get $S_0, S_1, S_0, S_1, S_0, S_1$ reverse change will be S_1, S_0, S_1, S_0 which is exactly the same sequence. So, the answer is a periodic DTMC can be reversible only if the period is 2.

(Refer Slide Time: 23:33)

The slide features a handwritten diagram and text. At the top left is the NPTEL logo. The text reads: "Necessity of period $d=2$ for a periodic DTMC to be reversible." Below this, there are two state transition diagrams. The left diagram shows a cycle of four states: S_0 , S_1 , S_2 , and S_{k-1} . Arrows indicate a clockwise cycle: $S_0 \rightarrow S_1 \rightarrow S_2 \rightarrow S_{k-1} \rightarrow S_0$. The right diagram shows a cycle of two states: S_0 and S_1 . Arrows indicate a clockwise cycle: $S_0 \rightarrow S_1 \rightarrow S_0$. Below the diagrams, the text states: "A periodic DTMC can be reversible if the period $d=2$. A DTMC with period $d > 2$ cannot be reversible." In the bottom left corner, there is a small video inset of a man in a light blue shirt.

This argument is enough to show, but answer a periodic DTMC, a DTMC with period d greater than 2 cannot be reversible due to the argument that we just made. Because the sequence S_0, S_1, S_2 will occur in the reverse direction and you can tell the difference. So, with that I will stop the discussion on reversibility.
