Sampling Distributions-I

(Refer Slide Time: 00:24)

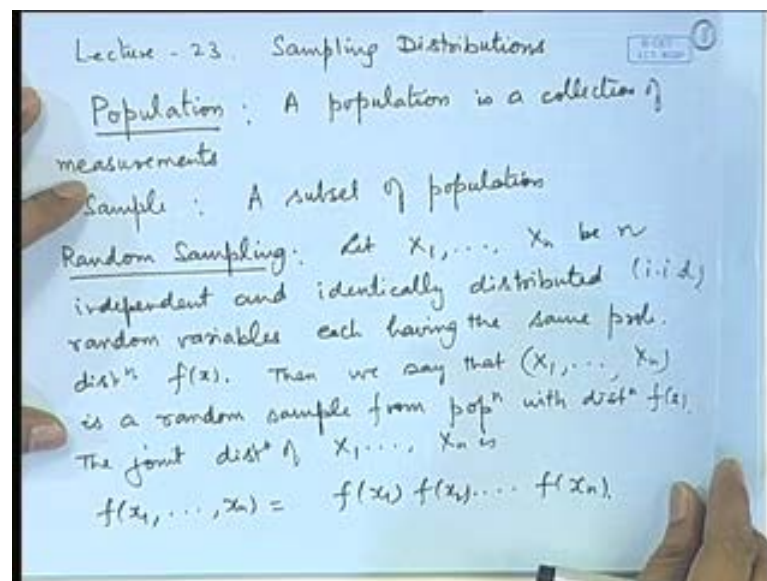

So, today we will introduce sampling distributions. So, first of all, we introduce, what we mean by a sample? What is a population? So, we introduce the term population. So, a population is a collection of measurements on certain characteristic. For example, if we are studying heights of people, then the measurements of the heights of our desired target population, that will be the statistical population. If we are interested in the lives of the people or longevity of the people, then, if we consider say, the total life, total age at death of a set of people, then that is our target population.

If we are interested in, say the number of smokers in a population then the characteristic of recording, that is whether a person is a smoker or not a smoker for a certain set that, is our target population. So, statistical population is a collection of measurements whether it is numerical or a qualitative measurements. A sample is a **a** subset of population. So, since it may not be possible to have the complete enumeration of the population, in various studies it is enough if we consider a certain sample of the population. So, a

general random sample which we consider in statistics, is taken in such a way that the probability of selecting each observation is same; however, **this is** the methods of doing sampling, it is a part of another topic called sampling theory or sampling techniques.

In this particular course, we are assuming that we already have a random sample and then we proceed with that. So, what is a random sample in the context of distribution theory? So, we say that let x_1, x_2, \dots, x_n be n independent and identically distributed; that is i.i.d random variables, each having the same probability distribution $f(x)$. Then, we say that x_1, x_2, \dots, x_n is a random sample from population with distribution $f(x)$. And the joint distribution of x_1, x_2, \dots, x_n is defined as $f(x_1, x_2, \dots, x_n)$ is equal to product of $f(x_1), f(x_2), \dots, f(x_n)$.

(Refer Slide Time: 04:15)

Any characteristic of the sample, we call it as a statistic. So, a function of random sample, let us say T ; that is T of x_1, x_2, \dots, x_n . This called a statistic. For example, we may consider \bar{x} , that is $\frac{1}{n} \sum x_i$, that is the sample mean. We may consider sample sum of squares from the deviation from the mean. We may consider $\frac{1}{n-1}$ of this, which we usually note by s^2 ; that is sample variance. We may be interested in say sample median. We have already talked about ordered statistics. So, that is also a statistics. Sample median, we may define to be the $x_{(\frac{n+1}{2})}$; that is $x_{(\frac{n+1}{2})}$, a third order statistics if n is odd; that means, the middle order statistics or if

n is even, then, we may take the mean of the middle two; that is $x_{n/2} + x_{n/2+1}$ plus 1 by 2.

We may consider say sample range; that is the difference between the largest and the smallest. So, these are Examples of certain statistics. And when we are dealing with a sample, we are interested in the characteristics and therefore, we will be interested in their distributions. So, the distributions of the statistics they are known as sampling distribution. So, we may formally define, a sampling distribution is the probability distribution of a statistic is called a sampling distribution. Now, as such here the distribution of x_1, x_2, \dots, x_n is known. So, the joint distribution of the sample is known to us.

So, if we consider any function of that T of x_1, x_2, \dots, x_n ; the derivation of the distribution relates to the techniques which we have defined in the previous lecture, that is for transformation of random vectors; that means, we may consider say one variable as T of x_1, x_2, \dots, x_n and we may define some other variables say u_1, u_2, \dots, u_{n-1} . So, that we have a n to n transformation and we may determine using any techniques for determining the sampling distribution.

(Refer Slide Time: 07:34)

Central Limit Theorem: Let x_1, x_2, \dots be a sequence of i.i.d. random variables with a mean μ and variance σ^2 ($< \infty$). Let $\bar{X}_n = \frac{1}{n} \sum_{i=1}^n X_i$. Then the limiting of $\frac{\sqrt{n}(\bar{X}_n - \mu)}{\sigma}$ is $N(0,1)$ as $n \rightarrow \infty$.

Remark: In practice $n \geq 30$ is considered to be large. If the original distⁿ is normal close to normal then for smaller n itself the approximation may be good.

$S_n = \sum_{i=1}^n X_i$ $\frac{S_n - n\mu}{\sqrt{n}\sigma} \xrightarrow{n \rightarrow \infty} N(0,1)$

However, there are some particular characteristics such as sample mean or the sample variance which plays very important role and here we will consider the distributions of that. So, one of the first results which is related to the distribution of the sample mean is a quite important result, in the sense that, it applies to a very large number of situations, it is known as Central Limit Theorem. So, let $x_1, x_2,$ and so on be a sequence of independent and identically distributed random variables. So, basically what we are saying is that, we are taking a sample with a large size. So, i.i.d random variables with a mean μ and variance σ^2 , we assume it to be finite. So, if we are assuming that say \bar{x}_n is the mean of the n observations. Then, the limiting distribution of $\sqrt{n}(\bar{x}_n - \mu)$ is normal $N(0, \sigma^2)$ as n tends to infinity.

That means, the standardized sample mean has a limiting standard normal distribution. Now, if we carefully look at the conditions of a theorem, this is pretty general. We are not making any assumption on the form of the distribution of x_i 's. All that we are assuming that the mean is given and the variance is given. In that case, the limiting distribution of the sample mean after a certain change of location and scale is standard normal provided the sample size is large. In fact, this is the result which places the normal distribution in the center of statistical theory.

What happens that in practice, when we are doing, when we are taking observations or measurements on certain thing, we are usually not taking one observation. For example, we may be measuring length of certain article. Suppose, if it is a physical experiment. So, we in place of taking one measurement, there is some measuring device and we take say thirty measurements and we take average of those measurements to say that, this is the actual estimate of the length of that Equipment.

So, in that case basically, what we are using is the \bar{x}_n , rather than individual x_i . The same thing is used at various places. For example, if we are looking at the average crop per field, then we are not taking individual crops rather than we are taking a sample of the fields and then we take the average; that means, the crops of the individual fields and then we take the average of that.

So, likewise in large number of practical situations, we are interested or we are actually using the mean rather than the individual observations. And therefore, the distribution of

the sample mean is what should be used. And this particular result, which is known as a central limit theorem, it says under very pretty general conditions, that the distribution is actually normal. Another thing that we should notice here is that, here we have assumed that the distributions; that means, the random variable x_1, x_2, \dots Etcetera are from the same population; that means, it is the sample from the same population. In fact, this central limit theorem has been further generalized; that means, we may lose the condition of say identically distributed or we may lose the condition of independence also and even then, under certain conditions the central limit theorem holds. However that is part of another study. Right now, we are concerned with this, sampling distribution, in which case, we take x_i 's to be independent and identically distributed random variables.

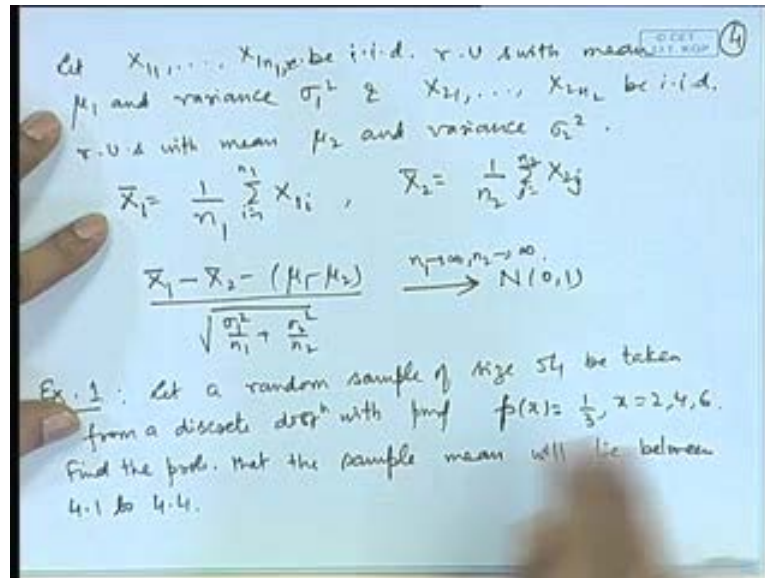

Now, one question may arise that how large n should be such that this approximation is good. So, in practice n greater than or equal to 30 is considered to be large. If the original distribution is normal or it is close to normal, then for smaller n itself the approximation may be good. One more point, earlier we have seen that binomial distribution was approximated to normal or the poisson distribution was approximated to normal. So, that is actually a special case of central limit theorem. Because, what is a binomial random variable? It is the sum of successes in individual trial. So, if you are taking x_1, x_2, \dots, x_n , so basically, it becomes the distribution of the sample sum. So, actually you can write an equivalent form also.

Suppose, I define $S_n = \sum_{i=1}^n x_i$, i is equal to 1 to n . Then, an Equivalent form is that, if we write $\frac{S_n - n\mu}{\sqrt{n}\sigma}$. Then, this will be converging to a standard normal random variable as n tends to infinity. So, the binomial approximation to normal is actually a special case of the central limit theorem. Similarly, the poisson distributions approximation to the normal is also a special case here, because a poisson random variable is the number of arrivals. So, if we are looking at the arrivals in the individual instants, how is were small that instant we may choose? Then, x is denoting the number of arrivals in the full length of the time which is becoming a sum and therefore, the sum of the observations must follow approximately normal distribution.

Now, in case of one sample we have straight forwardly for sample mean. Suppose, we have two samples, then the second sample mean may also have normal. And therefore, if

we use the linearity property of the normal distributions, then the differences etcetera may also follow a certain central limit theorem.

(Refer Slide Time: 14:41)

Let me give a generalization of this one. So, let say $x_{11}, x_{12}, \dots, x_{1n_1}$ be Etcetera. So, let me take n_1 only be i i d random variables, with say mean μ_1 and variance σ_1^2 and say $x_{21}, x_{22}, \dots, x_{2n_2}$, be i i d random variables with mean μ_2 and variance σ_2^2 . So, you consider the random variables say \bar{x}_1 which is actually the mean of the first sample. And \bar{x}_2 is equal to say mean of the second sample. Let me put j here. And construct the random variable $\bar{x}_1 - \bar{x}_2 - \mu_1 + \mu_2$ divided by square root $\sigma_1^2/n_1 + \sigma_2^2/n_2$. Then, this converges as n_1 tends to infinity to a normal $N(0,1)$; that is here n_1 tending to infinity and n_2 tending to infinity. So, this result is quite useful, the original central limit theorem and this results. To solve variety of probability problems where original probability distribution of the sum may be quite complicated **and** but using this, we can derive the probabilities. Let me give some example here. Let a random sample of size say 54 be taken from a discrete distribution with probability mass function say $p(x)$ is equal to $1/3$ for x equal to 2, 4, 6. Find the probability that, the sample mean will lie between say 4.1 to 4.4.

(Refer Slide Time: 17:46)

$$P(4.1 \leq \bar{X}_{54} \leq 4.4)$$

$$\mu = \frac{1}{3}(2+4+6) = 4. \quad E(X^2) = \frac{(4+16+36)}{3} = \frac{56}{3}$$

$$\sigma^2 = \frac{56}{3} - 16 = \frac{8}{3}, \quad n = 54$$

$$\frac{\sqrt{54}(\bar{X}_{54} - 4)}{\sqrt{8/3}} \rightarrow \underline{N(0,1)}$$

$$\approx P\left(\frac{\sqrt{54} \cdot 3}{8}(\bar{X}_{54} - 4) \leq Z \leq \frac{\sqrt{54} \cdot 3}{8}(4.4 - 4)\right)$$

$$= P(0.45 \leq Z \leq 1.8) = \Phi(1.8) - \Phi(0.45)$$

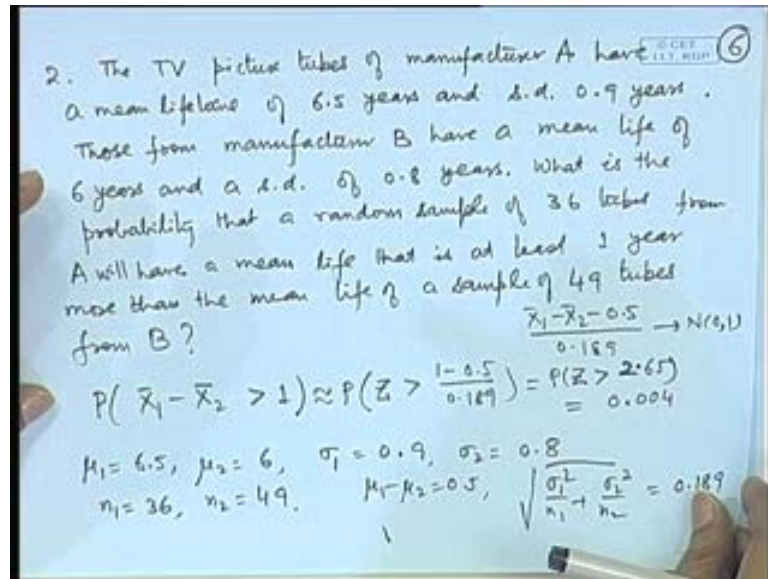

$$= 0.9641 - 0.6736 = 0.2905$$

So, basically we are interested to get the probability of 4.1 less than or equal to \bar{X}_n . So, here \bar{X}_n is \bar{X}_{54} less than or equal to 4.4. Now, this is a discrete uniform distribution centered at 2 and 6. If we look at the mean of this one, μ is $\frac{1}{3}(2+4+6)$ that is equal to 4. And if we look at the variance, so, we can check say expectation X^2 that is equal to $\frac{4+16+36}{3}$, that is $\frac{56}{3}$. So, variance of X that is equal to $\frac{56}{3} - 16$, that is $\frac{8}{3}$. And n is here 54. So, we have the distribution of $\frac{\sqrt{54}(\bar{X}_{54} - 4)}{\sqrt{8/3}}$ into $N(0,1)$. So, if we use this property here, the probability of \bar{X}_{54} lying between 4.1 to 4.4 is approximately same as, so, root of we may take it to the numerator. So, it becomes root of 54 into $\frac{3}{8}(\bar{X}_{54} - 4)$. So, this is the $4.1 - 4$ less than or equal to Z ; this is approximately $\frac{\sqrt{54} \cdot 3}{8}(4.4 - 4)$.

So, if we simplify these terms, it is probability of Z lying between 0.45 to 1.8 which is approximately. So, $\Phi(1.8) - \Phi(0.45)$. So, from the tables of the normal distribution, these values are 0.9641 minus 0.6736; that is equal to 0.2905; that is approximately 30 percent of the time the sample mean will lie between 4.1 to 4.14. Here, we notice that the original distribution is uniform. So, the distribution of \bar{X}_{54} will be very complicated. We have seen earlier, that the sum of two independent continuous uniform distributions is triangular distribution. If we take three of the independent continuous uniform distributions, the form is some sort of parabolic in nature. So, if we

take 54 such observations and try to find out the actual distribution that is very complicated. And here using the central limit theorem, easily we are getting an approximate value for this. And 54 is in fact, a large sample size and therefore, this approximation will be almost quite good.

(Refer Slide Time: 21:08)

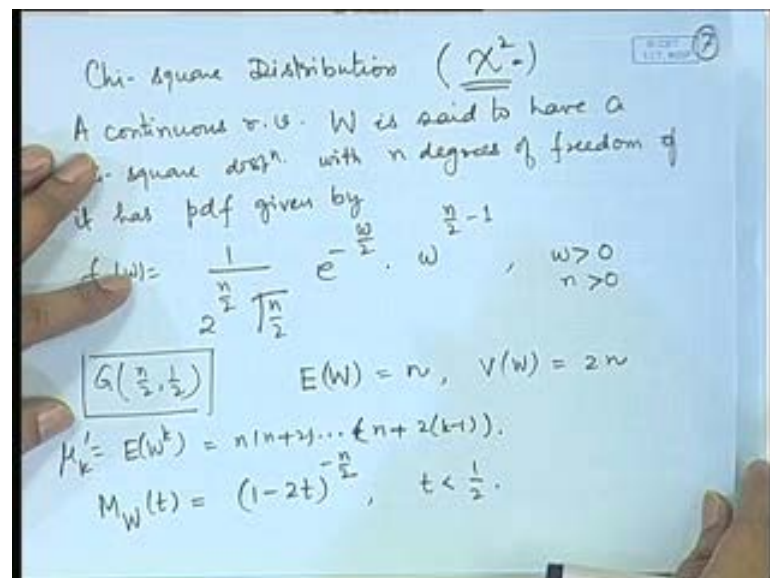

Let us take another example. The TV picture tubes of say manufacturer A have a mean life time of 6.5 years and standard deviation say 0.9 years. Those from manufacturer B have a mean life of 6 years and a standard deviation of 0.8 years. What is the probability that a random sample of say 36 tubes from A will have a mean life, that is at least one year more than the mean life of a sample of 49 tubes from B.

So, here we will apply the extended version of the central limit theorem, because we are dealing with the two samples. So, we can consider that $\bar{x}_1 - \bar{x}_2 - \mu_1 - \mu_2$ divided by $\sigma_1^2/n_1 + \sigma_2^2/n_2$ will be approximately standard normal distribution. So, here we see that, we are supposed to find out the probability of $\bar{x}_1 - \bar{x}_2$ greater than 1. Now, we look at the parameters here μ_1 is 6.5 μ_2 is 6 σ_1 is 0.9, σ_2 is 0.8, n_1 is equal to 36 and n_2 is equal to 49. So, if we calculate say $\mu_1 - \mu_2$; that is 0.5. And square root of $\sigma_1^2/n_1 + \sigma_2^2/n_2$ that is equal to 0.189.

So, $\bar{x}_1 - \bar{x}_2 - 0.5$ divided by 0.189 . It is approximately normal distribution. So, if we are to calculate this probability, we can approximate it by probability z greater than $1 - 0.5$ divided by 0.189 ; that is equal to probability z greater than $+2.65$. If we see from the tables of the normal distribution, this probability is only 0.004 . So, the probability that a random sample of size 36 from A will have a mean life at least one year more than the mean life of another sample of 49 from B is extremely small. So, here you see that, actually the mean life difference is only 0.5 here. So, we are expecting in the sample means to have difference of 1 . So, the probability of that is going to be very small now. Another point, that we notice here is that if the original distribution itself is normal, then $\frac{\bar{x} - \mu}{\sigma/\sqrt{n}}$ has exactly a standard normal distribution. So, approximation is exact when we have normal distribution. Central limit theorems are widely used in statistical theory.

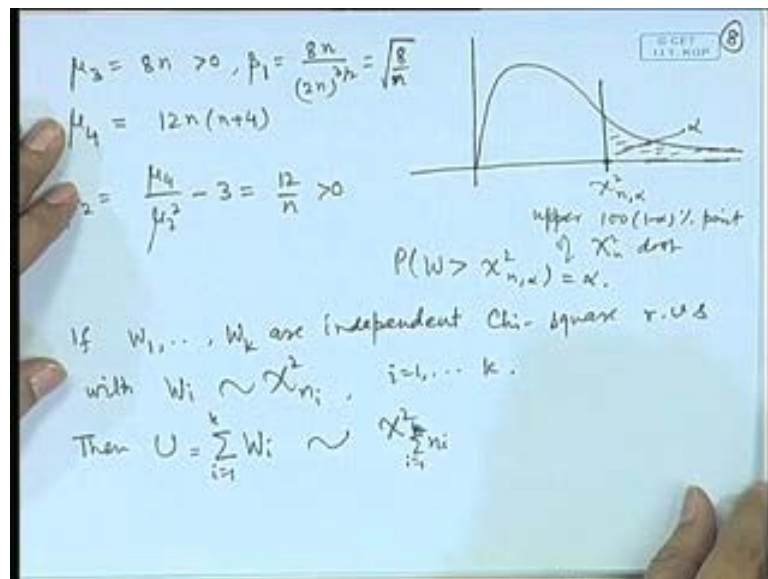

(Refer Slide Time: 25:59)

Now, we discuss another sampling distribution which is known as chi square distribution. And it is used as chi, Greek letter chi, so, chi square distribution. So, a continuous random variable say W is said to have a chi square distribution with n degrees of freedom, if it has probability density function given by say $f(w)$ equal to 1 by 2 to the power n by 2 gamma n by 2 e to the power minus w by 2 , w to the power n by 2 minus 1 where w is positive and of course, n has to be positive.

If we see carefully it is actually nothing, but a gamma distribution with parameters n by two and 1 by 2 . So, this is only a special case of gamma distribution. So, why we are calling it as a sampling distribution. So, we will show that this distribution arises in sampling from a particular population; that means, we have certain characteristic for which this will be the distribution. Before, doing those things let us look at the usual characteristics like mean variance and other things. So, since it is a gamma distribution, we already know the mean. It will be n by 2 by 1 by 2 , that is equal to n . So, the term which we are calling as a degrees of freedom is actually the mean of the chi square distribution. Similarly, if we look at the variance in gamma or lambda distribution the variance was r by lambda square. So, it becomes n by 2 divided by 1 by 2 square that is equal to twice n . So, that is two times degrees of freedom. We may write a general term, like μ_k prime that is equal to expectation of w to the power k ; that is n into n plus 2 and so on up to n plus 2 into k minus 1 . We may look at the moment generating function that is equal to 1 minus $2t$ to the power minus n by 2 , this is valid for t less than half.

(Refer Slide Time: 28:48)

In particular, we may look at the third central moment that is $8n$. So, obviously, it is a positively skewed distribution, since gamma distribution is positively skewed. So, of course, depending upon different values of n , you will have different shapes for the chi square variable. So, μ_4 , but of course, if we look at the major of symmetry, that is beta 1 that is $8n$ divided by $2n$ to the power 3 by 2 . So, it is becoming root 8 by n and as n

becomes large. This is approximately 0. Similarly, if we look at μ_4 , that is $12n$ into n plus 4 and the major of the kurtosis is μ_4 by μ_2 square minus 3 which is equal to 12 by n . So, it is positive. So, that means, the peak is higher than the normal but as n becomes large, this is approximately normal.

So, in fact as n becomes large, this is tending towards normality. That fact, we can see from here also because, it is $1 - 2t$ to the power minus n by 2 . Here, if I take limit as n tends to infinity, so, we can after certain adjustments show that, this will tend to the moment generating function of a normal variable. We will come to that later, after representation of chi square is known.

Now, depending upon the different values of n , the shape of this will be different. And since, it is a special case of gamma distribution, the tables of gamma distribution can be used to determine the probabilities. However, tables of chi square distribution are available for specific probabilities. So, if this probability say α , then the point on the axis is called chi square n α ; that is upper 100α $1 - \alpha$ percent point of chi square n distribution; that means, probability of W greater than chi square n α is equal to α .

Now, we see that, why this is a particular case of a sampling distribution. So, we will try to derive. So, since it is a special case of gamma distribution, we have already seen that in the gamma distribution, if the scale parameter is kept fixed, a certain additive property is satisfied. Therefore, if we consider, if say w_1, w_2, w_k are independent chi square random variables, with say w_i following chi square n_i , for i is equal to 1 to k . Then, say σ of w_i , i is equal to 1 to k , that will follow chi square σ of n_i . The proof is extremely simple because, if we apply the property that the moment generating function of the sum is the product of the individual moment generating functions, if the random variables are independent, then the distribution of the MGF of U will be product of the MGF's of w_i , which will be $1 - 2t$ to the power minus n_i by 2 . So, if we multiply out this will become σ n_i by 2 . So, the distribution of the sum of the chi squares is again a chi square and the degrees of freedom are added.

(Refer Slide Time: 33:03)

Let $X \sim N(0, 1)$. $f_X(x) = \frac{1}{\sqrt{2\pi}} e^{-x^2/2}$, $-\infty < x < \infty$

$Y = X^2$

$x = -\sqrt{y}$ $\frac{dx}{dy} = -\frac{1}{2\sqrt{y}}$ $|\frac{dx}{dy}| = \frac{1}{2\sqrt{y}}$

$x = \sqrt{y}$ $\frac{dx}{dy} = \frac{1}{2\sqrt{y}}$

$f_Y(y) = \begin{cases} 2 \cdot \frac{1}{\sqrt{2\pi}} e^{-y/2} \cdot \frac{1}{2\sqrt{y}}, & y > 0 \\ 0, & y \leq 0 \end{cases}$

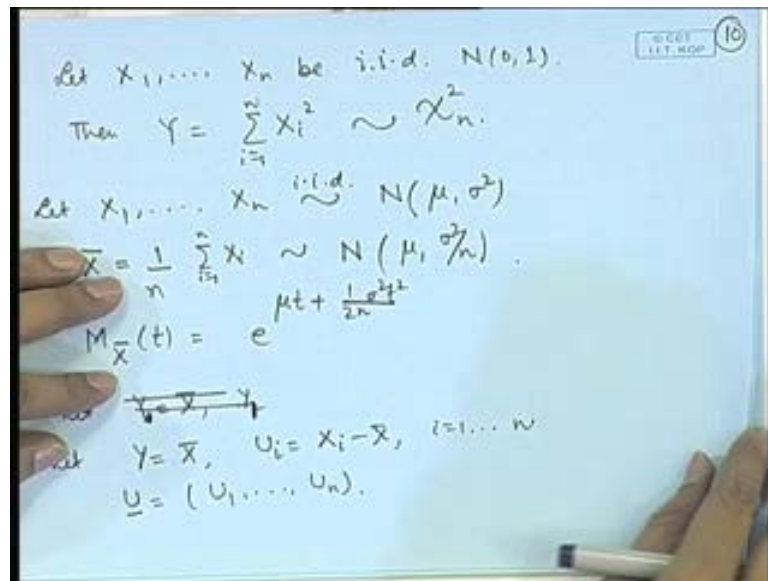

$= \frac{1}{2^{1/2} \Gamma(1/2)} e^{-y/2} y^{1/2 - 1}, y > 0$

So $Y \sim \chi^2_1$.

Next, we look at the following result. Let x follow normal $0, 1$. Let us define say Y is equal to x square. We want the distribution of Y . So, we look at the inverse transformation, it is a 2 to 1 transformation. The joint, the density of x is given to be 1 by root 2π e to the power minus x square by 2 where x lies between minus infinity to infinity x is equal to minus root y and x is equal to plus root y are two inverse images for any y positive. So, if we look at dx by dy term, that is minus 1 by 2 root y or plus 1 by 2 root y .

So, when we take absolute value of dx by dy in both the reasons, it is 1 by 2 root y . So, the density function of y is obtained as 1 by root 2π e to the power minus y by 2 , 1 by 2 root y . And second time, again the same term will come. So, we will write two times. This is for y positive and 0 for y less than or equal to 0 . So, this is Equal to 1 by 2 to the power half root π . We can write as $\Gamma(1/2)$ e to the power minus y by 2 y to the power minus 1 by 2 which, we can write as 1 by 2 minus 1 for y positive. So, if we look at the density of a general chi square distribution, here if we substitute n is equal to 1 , then we get these density function. This proves that the square of a standard normal variable is a chi square variable with one degree of freedom; that is y follows chi square on one degree of freedom.

(Refer Slide Time: 35:16)

So, let us consider say x_1, x_2, x_n independent and identically distributed, say standard normal random variables. Then, y is equal to $\sum_{i=1}^n x_i^2$, i is equal to 1 to n . This will follow chi square n . Since, we have already proved each of the x_i^2 that will be chi square 1, if x_1, x_2 and x_n are independent, then x_1^2, x_2^2, x_n^2 are also independent. Therefore, the distribution of the sum will be the chi squares added and since chi squares are satisfying an additive property, this becomes chi square n distribution.

Now, you see if x_1, x_2 , and x_n is a random sample from a standard normal variable then $\sum_{i=1}^n x_i^2$ is a statistic. And therefore, chi square becomes a sampling distribution. We will consider a further elaborate description of chi square in the next section. So, now, let us consider say x_1, x_2, x_n be a random sample from say normal μ, σ^2 . So, in place of normal $0, 1$, now let us consider normal μ, σ^2 . So, if we define \bar{x} as the mean, then by the linearity property, this will follow normal $\mu, \sigma^2/n$. Therefore, the moment generating function of \bar{x} will be $e^{\mu t + \frac{\sigma^2 t^2}{2n}}$. So, we prove the following result. Let us denote by say y_1 is equal to \bar{x} , y_2 and so, let us put say y is equal to \bar{x} and or let me change the notation, let say Y is equal to \bar{x} and say U_i is equal to $x_i - \bar{x}$ for i is equal to 1 to n . Let us use the vector notation U for u_1, u_2, u_n .

(Refer Slide Time: 38:15)

Then, we have the following theorem. Let x_1, x_2, \dots, x_n be a random sample from normal μ, σ^2 distribution. Then \bar{Y} and U are statistically independent; that means, \bar{X} is independent of $x_1 - \bar{X}, x_2 - \bar{X}, \dots, x_n - \bar{X}$. Now, to prove this result, we will use a moment generating function approach. We will show that the joint MGF of \bar{Y} and U at the point say s and t is equal to the moment generating function of \bar{Y} at s into the moment generating function of U at t , where t is equal to t_1, t_2, \dots, t_n . So, this is true for all s and all t . So, we need to evaluate the moment generating function of \bar{Y} and the individual moment generating functions. So, already the moment generating function of \bar{Y} , that is \bar{X} is given to us. So, $M_{\bar{Y}}(s) = e^{\mu s + \frac{1}{2} \sigma^2 s^2}$. Now, we calculate the moment generating function of U also, that is expectation of $e^{\sum_{i=1}^n t_i X_i - n \bar{E} \bar{X}}$; that is equal to expectation of $e^{\sum_{i=1}^n t_i X_i - n \bar{E} \bar{X}}$. At this stage, I will introduce some notation. So, this becomes expectation of $e^{\sum_{i=1}^n t_i X_i - n \bar{E} \bar{X}}$. Now, the second term here is $n \bar{E} \bar{X}$. So, we use a notation say \bar{t} as the mean of t_i 's. So, $n \bar{E} \bar{X}$ becomes $n \bar{t} \bar{X}$.

Now, once again since $\bar{X} = \frac{1}{n} \sum_{i=1}^n X_i$, we can again use it here. So, this becomes expectation of $e^{\sum_{i=1}^n t_i X_i - n \bar{t} \bar{X}}$, which is equal to expectation of $e^{\sum_{i=1}^n X_i(t_i - \bar{t})}$. Since, the random variables are independent X_1, X_2, \dots, X_n are independent random

variables expectation of a product becomes the product of the expectations. However, we notice that, these expectations are nothing but the moment generating functions of x_i at the point t_i minus \bar{t} .

(Refer Slide Time: 41:46)

The whiteboard shows the following derivation:

$$\begin{aligned}
 &= \prod_{i=1}^n M_{X_i}(t_i - \bar{t}) = \prod_{i=1}^n e^{\mu(t_i - \bar{t}) + \frac{1}{2}\sigma^2(t_i - \bar{t})^2} \\
 &= e^{\frac{1}{2}\sigma^2 \sum (t_i - \bar{t})^2} \dots (2) \\
 M_{Y,U}(s,t) &= E\left(e^{sY + \sum t_i U_i}\right) \\
 &= E\left(e^{\frac{s}{n} \sum X_i + \sum X_i(t_i - \bar{t})}\right) \\
 &= E\left(e^{\sum X_i(t_i - \bar{t} + \frac{s}{n})}\right) = E\left\{ \prod_{i=1}^n e^{X_i(t_i - \bar{t} + \frac{s}{n})} \right\} \\
 &= \prod_{i=1}^n E\left\{ e^{X_i(t_i - \bar{t} + \frac{s}{n})} \right\} = \prod_{i=1}^n M_{X_i}\left(t_i - \bar{t} + \frac{s}{n}\right)
 \end{aligned}$$

So, this is equal to product of the moment generating functions of x_i at t_i minus \bar{t} . Since, x_i 's are normal, we know these values. So, we substitute them here. This product from $i=1$ to n is equal to e to the power $\sum_{i=1}^n (\mu(t_i - \bar{t}) + \frac{1}{2}\sigma^2(t_i - \bar{t})^2)$. This is not μI , this is only $\mu \sum (t_i - \bar{t}) + \frac{1}{2}\sigma^2 \sum (t_i - \bar{t})^2$. So, now we apply this product here. So, the first term vanishes and the second term becomes e to the power $\frac{1}{2}\sigma^2 \sum (t_i - \bar{t})^2$.

So, we have calculated the right hand side here. That is $M_{Y,U}$ is calculated here. $M_{U,t}$ is also now calculated. Now, we calculate the joint MGF of Y and U at a point s and t . So, $M_{Y,U}$ at s, t . So, by definition of the joint MGF, it is equal to the expectation of e to the power $sY + \sum t_i U_i$. The second term has already been simplified; that is e to the power $\sum t_i U_i$ has already been simplified as e to the power $\sum X_i(t_i - \bar{t})$. So, we will use that here. It becomes expectation of e to the power $s \sum X_i + \sum X_i(t_i - \bar{t})$; that is Y is the mean. So, $\sum X_i$ by n plus the second term $\sum t_i U_i$, we are using the simplification that we did just now; that is $\sum t_i U_i$ is equal to $\sum X_i(t_i - \bar{t})$. We again, combine these terms here. So, this becomes expectation of e to the power

$\prod_{i=1}^n e^{-\frac{1}{2\sigma^2} (t_i - \bar{t} + \frac{s}{n})^2}$. So, this we Express as product i is equal to 1 to n e to the power $-\frac{1}{2\sigma^2} (t_i - \bar{t} + \frac{s}{n})^2$. And once again since x_i 's are independent random variables, expectation of the product becomes the product of the expectations. Product i is equal to 1 to n expectation of $e^{-\frac{1}{2\sigma^2} (t_i - \bar{t} + \frac{s}{n})^2}$. So, notice here that now, this has become MGF of x_i at the point $t_i - \bar{t} + \frac{s}{n}$ by n. So, it is product of the MGF's at the point $t_i - \bar{t} + \frac{s}{n}$ by n. So, once again making use of the fact that the x_i have a normal μ σ^2 distribution, we know the form of the MGF. So, we substitute it here.

(Refer Slide Time: 45:08)

$$= \prod_{i=1}^n \left\{ e^{-\frac{1}{2\sigma^2} (t_i - \bar{t} + \frac{s}{n})^2} \right\}$$

$$= e^{-\frac{1}{2\sigma^2} \sum_{i=1}^n (t_i - \bar{t} + \frac{s}{n})^2}$$

$$= M_Y(s) M_U(\bar{t})$$

So Y and U are independently dist.

Corollary: Let $X_1, \dots, X_n \stackrel{i.i.d.}{\sim} N(\mu, \sigma^2)$
 Then \bar{X} and S^2 are independent

That is equal to product i is equal to 1 to n e to the power $-\frac{1}{2\sigma^2} (t_i - \bar{t} + \frac{s}{n})^2$. So, now this is, if we apply this product here, e to the power $-\frac{1}{2\sigma^2} (t_i - \bar{t} + \frac{s}{n})^2$ becomes 0. And the second term, we will get e to the power $-\frac{1}{2\sigma^2} (t_i - \bar{t})^2$. Here, if we expand one term is $(t_i - \bar{t} + \frac{s}{n})^2 = (t_i - \bar{t})^2 + 2(t_i - \bar{t})\frac{s}{n} + \frac{s^2}{n}$. So, this we write here as $(t_i - \bar{t})^2 + \frac{s^2}{n} + 2(t_i - \bar{t})\frac{s}{n}$. The second term actually vanishes, because cross product term will give s by n into $(t_i - \bar{t})$. So, $\sum (t_i - \bar{t}) = 0$. So, if we utilize the relations one, so, the first term here is nothing but the MGF of Y at the point s and the second term from the equation number two is $M_U(\bar{t})$. So, we have proved that the joint MGF of Y and U is equal to the product of the MGF's of Y and U respectively. So, Y and U are independent.

So, as a consequence, we have the following corollary. That is, let x_1, x_2, \dots, x_n be a random sample from normal μ, σ^2 distribution. Then, \bar{x} and S^2 are independent. That is, in a random sampling from a normal distribution the sample mean and the sample variance are independently distributed. So, the proof follows immediately, if we notice that S^2 is a function of U . So, since \bar{x} and U are independent, therefore, \bar{x} and S^2 are independent.

The whiteboard shows the following derivation:

$$\begin{aligned}
 &= \prod_{i=1}^n M_{X_i}(t_i - \bar{t}) = \prod_{i=1}^n e^{-\mu(t_i - \bar{t}) + \frac{1}{2}\sigma^2(t_i - \bar{t})^2} \\
 &= e^{-\frac{1}{2}\sigma^2 \sum (t_i - \bar{t})^2} \dots (2) \\
 M_{\bar{Y}, U}(\lambda, \underline{t}) &= E\left(e^{\lambda \bar{Y} + \sum t_i U_i}\right) \\
 &= E\left(e^{\frac{\lambda}{n} \sum X_i + \sum X_i (t_i - \bar{t})}\right) \\
 &= E\left\{e^{\sum X_i \left(t_i - \bar{t} + \frac{\lambda}{n}\right)}\right\} = E\left\{\prod_{i=1}^n e^{X_i \left(t_i - \bar{t} + \frac{\lambda}{n}\right)}\right\} \\
 &= \prod_{i=1}^n E\left\{e^{X_i \left(t_i - \bar{t} + \frac{\lambda}{n}\right)}\right\} = \prod_{i=1}^n M_{X_i}\left(t_i - \bar{t} + \frac{\lambda}{n}\right)
 \end{aligned}$$

Now, we will show that, this is helpful to derive the distribution of S^2 . So, now we look at the following quantities. Consider say $\sum (x_i - \mu)^2$. So, here if we add and subtract \bar{x} , this becomes $\sum (x_i - \bar{x} + \bar{x} - \mu)^2$. So, if we divide it by σ^2 here, then we have this relationship. So, let us name these variables as say W is equal to W_1 plus W_2 say. So, this is W variable, this is W_1 variable, this is W_2 variable. So, now, if I have x_i 's following normal μ, σ^2 , then $(x_i - \mu) / \sigma$ follows normal $0, 1$. So, This implies that $(x_i - \mu) / \sigma$ follows chi square 1. And therefore, the sum of these, that is $\sum (x_i - \mu)^2 / \sigma^2$, that is W ; this will follow chi square distribution on n degrees of freedom.

Further, the distribution of \bar{x} is normal μ σ^2/n . So, from here we conclude that, $\bar{x} - \mu$ \sqrt{n} σ , this will follow normal 0 1 distribution. So, if i take the square $n(\bar{x} - \mu)^2 / \sigma^2$, so, this will follow chi square distribution on one degree of freedom. This is W_2 variable. Also W_1 and W_2 are independent. Because, W_1 is a function of s^2 and W_2 is a function of \bar{x} . We have already proved that \bar{x} and s^2 are independent. So, here we have written W_1 , a chi square n variable as a sum of two independent random variables of which, one of them is already a chi square.

(Refer Slide Time: 50:44)

Handwritten notes on a whiteboard:

$$= \prod_{i=1}^n \left\{ e^{-\mu(t_i - \bar{x} + \frac{\bar{x}}{n}) + \frac{1}{2}\sigma^2(t_i - \bar{x} + \frac{\bar{x}}{n})^2} \right\}$$

$$= e^{\mu s + \frac{1}{2} \frac{\sigma^2 s^2}{n} + \frac{1}{2} \sigma^2 \sum (t_i - \bar{x})^2}$$

$$= M_Y(s) M_U(\bar{x})$$

So Y and U are independently distd.

Corollary: Let $X_1, \dots, X_n \stackrel{i.i.d.}{\sim} N(\mu, \sigma^2)$
Then \bar{X} and S^2 are independent

So, now if we use the moment generating function property that is $M_{W_1+2} t$ will be equal to $M_{W_1} t$ into $M_{W_2} t$. So, this means that $M_{W_1} t$ is the ratio of $M_{W_1+2} t$ divided by $M_{W_2} t$. Since, the MGF of a chi square variable is known, there is $1 - 2t$ to the power $n/2 - 1$ divided by $1 - 2t$ to the power $n/2 - 1$, because W_2 is a chi square is 1. So, this becomes $1 - 2t$ to the power $n - 1$ for t less than half; that means, W_1 , that is $\sum (x_i - \bar{x})^2 / \sigma^2$ which we can also write as $(n-1) S^2 / \sigma^2$. This follows a chi square distribution on $n - 1$ degree of freedom.

So, this means that chi square is a distribution of the sample variance after certain scaling. So, this shows that chi square is a sampling distribution. Either, we consider a

standard normal random variable, so, sum of squares of n independent random variables normal random variables is chi square on degrees of freedom or if we are considering arbitrary normal random variables, then if we consider the scaled distribution of the sample sum of squares from the deviation, that is $n - 1 S^2$ by σ^2 , then that is chi square on $n - 1$ degrees of freedom.

Here, we want to clarify one question that, although this is sum of n variables, in fact, each of $x_i - \bar{x}$ is a normal random variable. In fact $x_i - \bar{x}$ will follow a normal distribution with mean 0, because x_i has mean μ and \bar{x} has mean μ . And variance will become $\sigma^2 \left(1 + \frac{1}{n}\right)$. So, it is a sum of n squares of random normal random variables, but this is not independent. Because, $\sum (x_i - \bar{x}) = 0$. So, only $n - 1$ of these are dependent; that is why, the degrees of freedom are here $n - 1$. So, in some sense these degrees of freedom can be related to the fact that, a general chi square random variable is sum of squares of n independent squares of standard normal variables. So, if when we consider any other, then it need not be.

So, we have established here chi square as a sampling distribution. And in particular, if we are interested to find out certain statement about S^2 , then we can answer that. For example, if we look at expectation of W_1 , then it is equal to $n - 1$. So, expectation of $n - 1 S^2$ by σ^2 follows, so, that is equal to $n - 1$. So, this means expectation of S^2 is equal to σ^2 . So, this means that on the average, that is S^2 that is the $\frac{\sum (x_i - \bar{x})^2}{n - 1}$ is unbiased for σ^2 not divided by n . And that is why, in particular, we consider sample variance as where the divisor is $n - 1$, not n because this is coming as an unbiased estimator for σ^2 . In the inference course, we will deal in detail about the criteria of unbiasedness for...

In the next lectures, we will take up other sampling distribution such as t and f distributions. So, today we will stop here.
