Invariance – II

So, let us continue the discussion on the equivariant estimators and maximal invariance, I had considered one example of the finding out maximal invariant let me take one or two more examples also.

(Refer Slide Time: 00:35)

So, let us consider say again x as n dimensional Euclidean space and G is the group of scale transformations. So, I am considering for n points then g_c of x is equal to $c \times x_1, c \times x_2, \dots, c \times x_n$, where c is any positive real number. In this case $T(x)$ is equal to x_2/x_1 and so on x_n/x_1 this is a maximal invariant. Once again you can see that as x_2 goes to $c \times x_2$, x_1 goes to $c \times x_1$ so, this ratio becomes same as x_2/x_1 . x_n goes to $c \times x_n$, x_1 goes to $c \times x_1$ so, the ratio goes to x_n/x_1 etcetera. So, these are all this is an invariant function. So, clearly $T(x)$ is

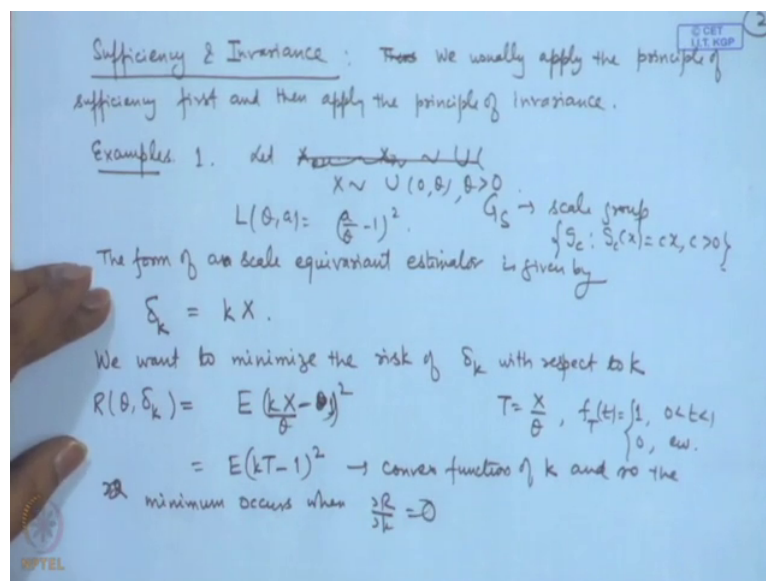

invariant and also if I take two points Tx is equal to Ty , then what I get x_2 by x_1 is equal to y_2 by y_1 , x_3 by x_1 is equal to y_3 by y_1 and soon x_n by x_1 is equal to y_n by y_1 .

Then this implies x_2 is equal to $y_2 x_1$ by y_1 , x_3 by x_1 is equal to $y_3 x_1$ by y_1 and so on x_n is equal to $y_n x_1$ by y_1 so this is c . So, this implies that x is equal to gc of y where we have chosen c to be x_1 by y_1 so, T is maximal invariant. Let us take another example say x is equal to say R_n and G is the group of all n factorial permutations of coordinates of x . Then Tx is equal to order statistics x_1, x_2, \dots, x_n this is maximal invariant. (No audio from: 03:30 to 03:39) Now, let us look at the importance of invariance in determining the best as I mentioned earlier that we want to use this concept to reduce the class of available estimators. And in that reduced class if it is possible to find the best one then we are having some sort of optimal estimator in that class.

Now, when we start the reduction then we have to find out the equivariant estimator we have seen one example here in the binomial case, the condition that we are getting here is that we should have T of $n - x$ is equal to $1 - T$ of x in the case of uniformed distribution we got the form of the equivariant estimator as a multiple of x . Now, if you take multiple of x then you realize here for example, $2x$ is unbiased it is also the method of moments estimator for this problem. But suppose I have n observations x_1, x_2, \dots, x_n in that case if I straightforwardly apply the concept of invariance then the estimator will turn out to be a function of it will turn to be x_1 into a function of x_2 by x_1 , x_3 by x_1 and soon.

On the other hand we had seen that the maximum likelihood estimator is x_n , the complete sufficient statistics is x_n . Now, in that case why not we restrict attention firstly to the sufficient statistics and then we apply the concept of invariance.

(Refer Slide Time: 05:36)

So, let me justify this thing sufficiency and invariance. So, there is a natural question that when the two criteria of sufficiency and invariance are there then which one should be applied first, can the applications of these in any order give the same answer or that will lead to the same solution etcetera? The general answer to these questions have been attempted by many researchers and under certain conditions certain results have been obtained. But we will follow a practical approach here, in most of the estimation problems we usually deal with convex loss functions. If the loss function is convex, the class of estimator which is based on the sufficient statistics supersedes or you can say given any estimator, which is not based on the sufficient statistics.

We can find an estimator which is better than that using the Rao-Blackwell theorem. Therefore, we can restrict attention to the class of estimators which are based on sufficient statistics. Now, if we apply the invariance on this class of estimators then we are considering much smaller class so, we will follow this approach here. So, we usually apply the principle of sufficiency first and then apply the principle of invariance, so let us see in certain problems when the group of transformations is transitive we may actually end up with getting the best equivariant estimator.

So, let us start with the uniform distribution problem. (No audio from: 07:58 to 08:11) Let me firstly consider this X following uniform $0, \theta$ problem which I introduced earlier. We got the form of the group was a scale group that is $g \circ g \circ X$ is equal to cX where c is positive

here theta is positive. The form of a scale equivariant estimator is given by let me use the term d_k that is equal to k times X . We want to minimize the risk of d_k with respect to k so, let us consider the risk of d_k that is equal to expectation of $kX - \theta$ square. Let us substitute say T is equal to X/θ , then what is the distribution of T that is uniform $0, 1$.

So, we can write it as expectation of $kT - 1$ square that means the risk function of the best of the equivariant estimator is independent of the parameter. Now, this is true because this is scale group of transformations is a transitive group. Because if I consider any two points θ_1 and θ_2 on the positive real line then, they can be reached from the other one. For example, I take θ_1 is equal to 2 and θ_2 is equal to 3 then if I choose c is equal to $3/2$ then 3 by 2 times 2 is equal to 3 that means there exist a transformation so that I can reach θ_2 from θ_1 . Therefore, the risk function will be constant and therefore, we can find out the best choice here.

(Refer Slide Time: 11:27)

$$\frac{\partial R}{\partial k} = 0 \Rightarrow 2 E(kT-1)T = 0$$

$$\Rightarrow k = \frac{E(T)}{E(T^2)} = \frac{1/2}{1/3} = \frac{3}{2}$$

So $\frac{3}{2}X$ is the best scale equivariant estimator of θ .

$d_1 = 2X = \delta_2$ is Method of moment estimator of θ .
 $d_2 = X = \delta_1$ is MLE of θ .
 $d_3 = \frac{3}{2}X = \delta_{3/2}$ is BSE of θ .

is better than both d_1 & d_2 .

$R(\theta, d_k) = E((kT-1)^2) = k^2 E(T^2) - 2k E(T) + 1$
 $= \frac{k^2}{3} - \frac{2k}{2} + 1 = \frac{k^2}{3} - k + 1$

$R(\theta, d_1) = R(\theta, \delta_1) = \frac{1}{3} - 2 + 1 = \frac{1}{3}$
 $R(\theta, d_2) = R(\theta, \delta_2) = \frac{4}{3} - 2 + 1 = \frac{1}{3}$
 $R(\theta, d_3) = R(\theta, \delta_{3/2}) = \frac{9}{12} - \frac{3}{2} + 1 = \frac{3}{4} - \frac{3}{2} + 1 = \frac{1}{4} < \frac{1}{3}$

So, this is now naturally a convex function of k and so, the minimum occurs when ∂R by ∂k is equal to 0. Now, this ∂R by ∂k is equal to 0 you can calculate ∂R by ∂k that will give us twice expectation $kT - 1$ into T is equal to 0 this means k is equal to expectation of T by expectation of T square. Now, in the case of uniform distribution the mean is half and expectation T square is $1/3$ that is equal to $3/2$. So, $3/2 X$ is the best scale equivariant estimator of θ . Now, let us just have a comparison between various

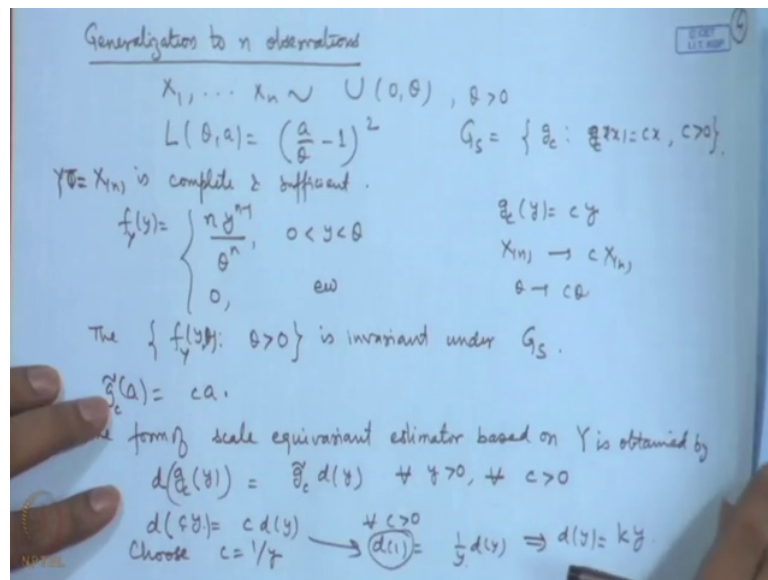

estimators for this problem. See let me give the notations here say d_1 that is $2X$ which is actually equal to δ_2 under this notation because δ_k is kX so, this is method of moments estimator here. (No audio from: 12:42 to 12:49)

And d_1 sorry d_2 that is equal to X that is equal to δ_1 is the maximum likelihood estimator of θ . And this is d_3 that is equal to $\frac{3}{2}X$ that is actually δ_3 by $\frac{2}{3}$ this is the best scale equivariant estimator of θ . Naturally d_3 is better than both d_1 and d_2 also let us compare d_1 and d_2 what is the risk of d_1 that is equal to expectation of 2^2 . So, actually we have the general form here we can calculate the risk function of δ_k that is expectation of $kT - 1$ square that is equal to k^2 expectation of T^2 minus twice k expectation of T plus 1 that is equal to k^2 expectation of T^2 is $\frac{1}{3}$ minus twice k expectation of T is $\frac{1}{2}$ plus 1 that is equal to k^2 by $\frac{1}{3}$ minus k plus 1.

So, from here the risk function of the method of moments estimator that will be equal to 4 by $\frac{1}{3}$ minus 2 plus 1 that is equal to $\frac{1}{3}$. The risk function of d_2 that is the maximum likelihood estimator that is the risk of δ_1 that is equal to 1 by $\frac{1}{3}$ minus 1 plus 1 that is equal to $\frac{1}{3}$. And the risk of d_3 that is the best scale equivariant estimator that is obtained by putting k equal to $\frac{3}{2}$ that is equal to 9 by $\frac{1}{3}$ into $\frac{1}{3}$ minus 3 by $\frac{2}{3}$ plus 1 so, that is equal to $\frac{1}{4}$ which is less than $\frac{1}{3}$. So, in this particular case the method of moments estimator and the maximum likelihood estimators they have the same risk and the best scale equivariant estimator is better than both of them.

So, here you can see the concept of invariance helps us in reducing the mean squared error because here, the risk criteria is actually the mean squared criteria mean squared error criteria.

(Refer Slide Time: 16:12)

Now, I will generalize this problem here I have considered only one observation from the uniform distribution. Now, in place of one observation suppose I have n observations let us consider generalization to n observations. If I have generalization to n observations that is $X_1 \times X_2 \times \dots \times X_n$ follows uniform $0, \theta$, the last in estimating θ is once again the same I am considering to keep the problem invariant the group of transformations is the scale group of transformations. (No voice from: 16:42 to 16:52) Now, here X_n is let me call it say T is complete and sufficient rather let me call it y . And we know the distribution of y the distribution of y is $n y^{n-1}$ to the power n minus 1 by θ^n to the power n .

Then the distributions $f_Y(y; \theta)$ where $\theta > 0$, they will remain invariant because if I consider the distribution of y see if I take $g_c(y) = cy$ then that will be equal to $c y$. Because if each of the observations is shifted by c then X_n that is the maximum will also be shifted by c . So, X_n goes to $c X_n$ and therefore, θ will go to $c \theta$ for this density also therefore, this density family of distribution is invariant under the scale group of transformations. And same thing will happen to the a also that is $g_c(a) = ca$ this will become equal to ca θ goes to $c \theta$ and a goes to ca .

So, we can consider the form of scale equivariant estimator based on y because this is the complete sufficient statistics. So, rather than starting from $X_1 \times X_2 \times \dots \times X_n$ we will initially restrict attention to X_n that is the X_n that is the sufficient statistic. So, this is obtained by considering the condition that is $d(g_c(y)) = g_c(d(y))$ for all y and for all c . Now,

this condition gives d of c y is equal to c of d y so, you can choose c is equal to 1 by y. So, there is no invariant here actually no maximal invariant here you will get d of 1 is equal to 1 by y d of y this implies d of y is of the form this d 1 is a constant a constant times y.

(Refer Slide Time: 20:14)

The form of a scale equivariant estimator is

$$\delta_k(Y) = \underline{kY} \quad \left(\begin{array}{l} \delta_1 = Y \text{ is MLE of } \theta \\ \delta_{\frac{n+1}{n}} = \frac{n+1}{n} Y \text{ is UMVUE of } \theta \end{array} \right)$$

$$R(\theta, \delta_k) = E\left(\frac{kY}{\theta} - 1\right)^2$$

$$= E(kT - 1)^2 \rightarrow \text{convex fn. of } k.$$

$\triangleright R$ is minimized w.r.t k if $\frac{\partial R}{\partial k} = 0$

$$\frac{\partial R}{\partial k} = 2 E(kT - 1) T = 0$$

$$\Rightarrow k = \frac{E(T)}{E(T^2)} = \frac{n/(n+1)}{n/(n+2)} = \frac{n+2}{n+1}$$

So $\delta_{\frac{n+2}{n+1}} = \frac{n+2}{n+1} Y$ is the BSE estimator of θ .

$T = \frac{Y}{\theta}, f(t) = \begin{cases} n t^{n-1}, & 0 < t < 1 \\ 0, & \text{else} \end{cases}$

$$E(T) = \int_0^1 n t^n dt = \frac{n}{n+1}$$

$$E(T^2) = \int_0^1 n t^{n+1} dt = \frac{n}{n+2}$$

So, we can write the form of a scale equivariant estimator is then let us call it delta k of y is equal to k times of y. In fact if I consider delta 1 that is equal to Y this is the maximum likelihood estimator and if I take delta is equal to n plus 1 by n that is n plus 1 by n Y this is the minimum variance unbiased estimator of theta so these two things are known to us. Now, let us try to see whether I get something else by considering the minimization of the risk function with respect to k. So, let us consider the risk function of delta k that is equal to expectation of k Y by theta minus 1 square. See once again we can look at this density if I define say T is equal to Y by theta then the density of T is nothing but n t to the power n minus 1 0 less than T less than 1 0 otherwise because this is the density of y.

So, if I consider the density of y by theta then 1 by theta d y will be equal to d T so, this density reduces to n t to the power n minus 1. So, if I look at expectation of T that is equal to integral n t to the power n d t 0 to 1 that is equal to n by n plus 1. And expectation of T square turns out to be 0 to 1 n t to the power n plus 1 d t that is equal to n by n plus 2 so, this is equal to expectation of k T minus 1 square. If we consider the minimization with respect to k R is minimized with respect to k if del R by del k equal to 0 why because this is nothing but a convex function of k this is convex function of k.

So, this del R by del k this gives twice expectation k T minus 1 into T equal to 0 that means k is equal to expectation of T by expectation of T square and that is equal to n by n plus 1 divided by n by n plus 2 that is equal to n plus 2 by n plus 1 so, delta of n plus 2 by n plus 1 that is n plus 2 by n plus 1 y is the best scale equivariant estimator of theta. Once again we can look at the relative risk comparison or risk improvement here naturally here you have the coefficient 1 here you have coefficient n plus 1 by n and here you have n plus 2 by n plus 1 so, this is the best. That is the risk of this will be the smaller than both of this now let us look at the overall comparison of the risk values here.

(Refer Slide Time: 24:10)

The image shows handwritten mathematical derivations on a blue background. The equations are as follows:

$$R(\theta, \delta_k) = k^2 E T^2 - 2k E T + 1$$

$$= \frac{n}{n+2} k^2 - \frac{2n}{n+1} k + 1.$$

MLE \rightarrow

$$R(\theta, \delta_1) = \frac{n}{n+2} - \frac{2n}{n+1} + 1 = \frac{n^2 + n - 2n^2 - 4n + n^2 + 3n + 2}{(n+1)(n+2)}$$

$$= \frac{2}{(n+1)(n+2)}$$

$$R(\theta, d_{UU}) = \frac{n}{n+2} \cdot \frac{(n+1)^2}{n^2} - \frac{2n}{n+1} \cdot \frac{n+1}{n} + 1$$

$$= \frac{n^2 + 2n + 1}{n(n+2)} - 1 = \frac{1}{n(n+2)}$$

$$R(\theta, d_{UU}) = \frac{n}{n+2} \cdot \frac{(n+1)^2}{(n+1)^2} - \frac{2n}{n+1} \cdot \frac{n+1}{n+1} + 1$$

$$= \frac{n^2 + 2n - 2n^2 - 4n + n^2 + 2n + 1}{(n+1)^2} = \frac{1}{(n+1)^2}$$

So, what is the value of R theta delta k that is k square expectation of T square minus twice k expectation of T plus 1 that is equal to n by n plus 2 k square minus twice n by n plus 1 k plus 1. So, if I look at the risk of say the maximum likelihood estimator here k equal to 1 so, I get n by n plus 2 minus twice n by n plus 1 plus 1 so, you can simplify this that is equal to n square plus n minus twice n square minus 4 n plus n square plus 3 n plus 2 divided by n plus 1 into n plus 2 so this get simplified that is equal to 2 divided by n plus 1 by n plus 2. If we look at the risk of the unbiased estimator minimum variance unbiased estimator then that is equal to it is obtained by the value k equal to n plus 1 by n here.

So, here if we substitute that we get n by n plus 2 n plus 1 square by n square minus twice n by n plus 1 into n plus 1 by n plus 1 so, here these terms cancelled out and we get here n square plus 2 n plus 1 divided by n into n plus 2 this is minus 1 because this is minus 2 plus 1

that is equal to once again 1 by n into n plus 2. So, naturally you can see that this is greater than let us also look at the risk of the best scale equivariant estimator that is equal to n by n plus 2 into n plus 2 square by n plus 1 square minus twice n by n plus 1 into n plus 2 by n plus 1 plus 1 so this can be simplified that is equal to n square plus 2 n minus twice n square minus 4 n plus n square plus 2 n plus 1 divided by n plus 1 square 1 by n plus 1 square.

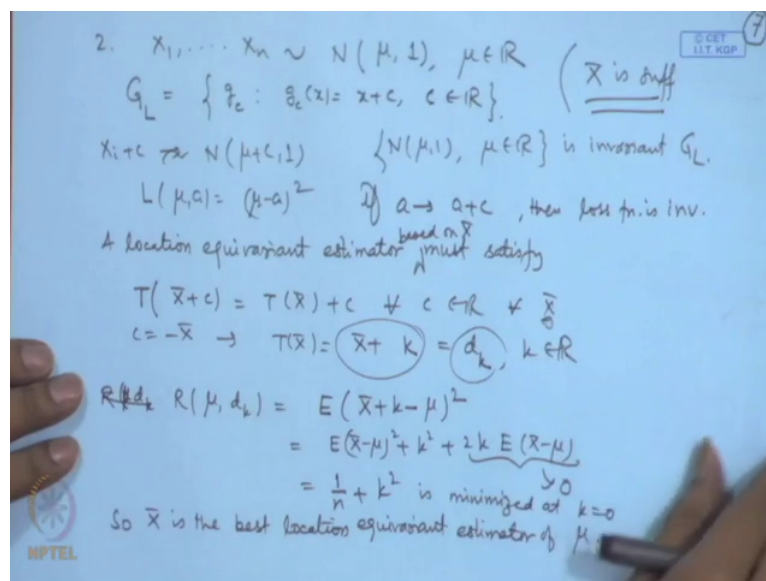

(Refer Slide Time: 27:27)

$$\begin{aligned}
 &= \frac{2}{(n+1)(n+2)} \\
 du) &= \frac{n}{n+2} \cdot \frac{(n+1)^2}{n^2} - \frac{2n}{n+1} \cdot \frac{n+1}{n} + 1 \\
 &= \frac{n^2 + 3n + 1}{n(n+2)} - 1 = \frac{1}{n(n+2)} \\
 ds) &= \frac{n}{n+2} \cdot \frac{(n+1)^2}{n^2} - \frac{2n}{n+1} \cdot \frac{n+1}{n} + 1 \\
 &= \frac{n^2 + 3n + 1}{n(n+2)} - \frac{2n^2 - 2n + n^2 + 2n + 1}{n(n+2)} \\
 &= \frac{n^2 + 3n + 1 - 2n^2 + 2n - n^2 - 2n - 1}{n(n+2)} \\
 &= \frac{-2n^2 + 4n}{n(n+2)} = \frac{2n(n-2)}{n(n+2)} = \frac{2(n-2)}{n+2}
 \end{aligned}$$

$\left(\frac{1}{(n+1)^2} < \frac{1}{n(n+2)} \right)$
 So $ds < du$
 $\frac{2}{(n+1)(n+2)} > \frac{1}{n(n+2)}$
 $2n^2 + 4n > n^2 + 2n + 2$
 $n^2 + 2n > 2$
 $du < ds$

So, if we compare now this 1 by n plus 1 square less than 1 by n into n plus 2 because this is n square plus 2 n and this is n square plus 2 n plus 1 so d b S is better than d u m. Similarly, if I compare the MLE and the UMVUE then 2 by n plus 1 into n plus 2 and 1 by n into n plus 2 let us look at the comparison here. So, this term if I multiply I get twice n square plus 4 n and here I get n square plus 3 n plus 2 so, if I put greater than this is reducing to n square plus n greater than 2 so, this condition is true that means d U M is better than d M L. So, in this particular case the best scale equivariant estimator turns out to be the best among the three given estimators.

(Refer Slide Time: 28:56)

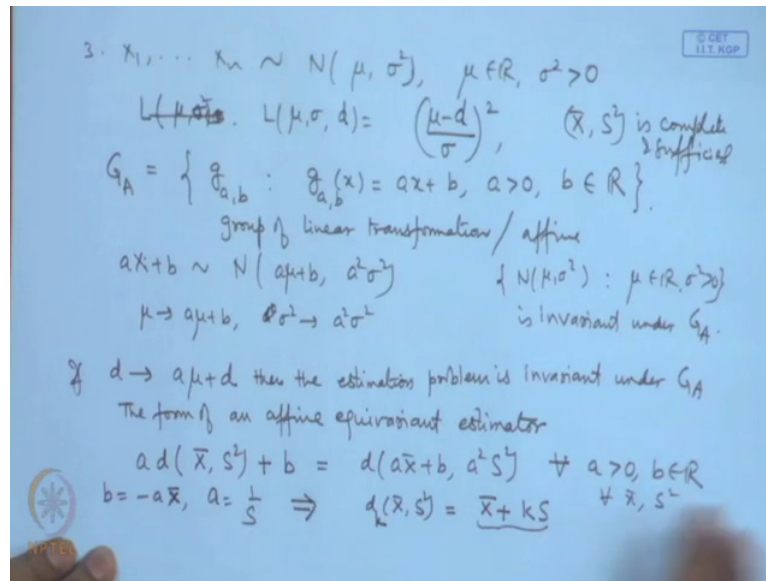

Let us take the normal distribution case $x_1 \times 2 \times n$ follows normal μ where μ is a real number we consider the group of translations or the location transformations g_c of x is equal to x plus c where c is any real number. Now, you observe here that X_i plus c that will follow normal μ plus c so, if μ is a real number then μ plus c is also a real number so, the family is invariant this family is invariant under the location group. Let us take the loss function here as μ minus a square now if μ goes to μ plus c , a should go to a plus c so if I take a going to a plus c then the loss function remains invariant and therefore, the estimation problem is invariant.

So, now let us find out the form of a location equivariant estimator this must satisfy now in this problem \bar{X} is sufficient. So, we will restrict attention to the distribution of \bar{X} based on \bar{X} . So, we will have T of \bar{X} plus c is equal to T of \bar{X} plus c for all c and for all \bar{X} so you choose c is equal to minus \bar{X} so, you will get T of \bar{X} is equal to \bar{X} plus a constant so, we call it say d_k where k is any real number. So, this is the form of a location equivariant estimator that it is \bar{X} plus a constant.

So, if I consider the risk function of this, that is equal to expectation of \bar{X} plus k minus μ whole square that is equal to expectation of \bar{X} minus μ square plus k square plus twice k expectation of \bar{X} minus μ this is 0 so, you are left with $1/n$ plus k square this is minimized at k equal to 0. So, \bar{X} is the best location equivariant estimator of μ .

(Refer Slide Time: 32:30)

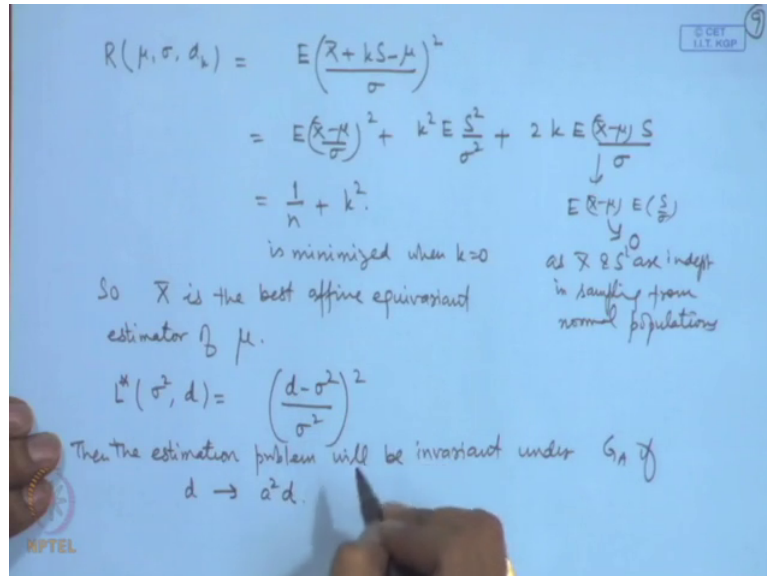

Let us generalize this problem; I consider here the variance also to be unknown $x \ 1 \times 2 \times n$ following say normal μ σ^2 . Now, we maintain the same loss function no sorry we change the loss function as $\mu - d$ by σ^2 whole square. Let us consider the group of transformations which are linear or affine (No audio from: 33:20 to 33:27) $aX + b$ where a is a positive number and b is any real number this is called group of linear transformations or affine transformations so, we will use the notation g_a . Now, under this the distribution of $aX + b$ is normal $a\mu + b$ $a^2\sigma^2$ so, $a\mu + b$ is another real number $a^2\sigma^2$ is positive therefore, the family is invariant.

The family of normal μ σ^2 distributions this is invariant under the group g_a . Naturally you are seeing that μ goes to $a\mu + b$ σ^2 goes to $a^2\sigma^2$ therefore, if I want to consider the let me put here d then d should go to $a\mu + d$. Then the estimation problem is invariant, (No audio from: 34:53 to 35:04) then the estimation problem is invariant under the group g . Now, to derive the form of an affine equivariant estimator (No audio from: 35:13 to 35:22) let us consider the form of an affine equivariant estimator then you will get d of \bar{X} S^2 so, here in this problem \bar{X} and S^2 is complete and sufficient.

So, $a d \bar{X} S^2 + b$ is equal to d of $a\bar{X} + b$ $a^2 S^2$ for all a and for all b and for all \bar{X} and S^2 . So, you choose b is equal to $-a\bar{X}$ and a is equal

to 1 by S, then this will give us d of X bar S square is equal to X bar plus some constant times S. So, this is the form of an affine equivariant estimator let us look at the risk function here.

(Refer Slide Time: 36:55)

Let us consider the risk function of d k that is equal to expectation of X bar plus k S minus μ by σ whole square that is equal to expectation of X bar minus μ by σ whole square plus k square expectation of S square by σ square plus twice k expectation of X bar minus μ S by σ . Now, in the sampling from normal distribution we know that X bar and S square they are independently distributed. So, this term will become 0 because this will become expectation of X bar minus μ into expectation of S by σ and this is 0 as X bar and S square are independent in sampling from normal populations.

So, this term simply becomes 1 by n plus k square expectation of S square is σ square so, this is simply one. Once again this is minimized when k equal to 0 so, X bar is the best affine equivariant estimator of μ . Suppose I take the loss function here that means the problem is of estimating σ square. If I consider this then the estimation problem remains invariant under the affine group if d goes to a square d , because σ square goes to a square σ square so, this will get this will remain invariant if d goes to a square d .

(Refer Slide Time: 39:47)

The form of an affine equivariant estimator for σ^2

$$\delta(a\bar{X} + b, a^2 S^2) = a^2 \delta(\bar{X}, S^2)$$

$$b = -a\bar{X}, a = \frac{1}{S} \Rightarrow \delta_k(\bar{X}, S^2) = k S^2, k > 0$$

$$R(\sigma^2, \delta_k) = E\left(\frac{k S^2 - \sigma^2}{\sigma^2}\right)^2$$

$$= E(kW - 1)^2$$

$$\frac{\partial R}{\partial k} = 2 E(kW - 1) W = 0$$

$$\Rightarrow k = \frac{E(W)}{E(W^2)} = \frac{n-1}{n+1}$$

So $\frac{n-1}{n+1} S^2 = \frac{1}{n+1} \sum (X_i - \bar{X})^2$ is the best affine equivariant estimator of σ^2 .

$S^2 = \frac{1}{n-1} \sum (X_i - \bar{X})^2$
 $\frac{\sigma^2}{S^2} = W$
 $E(W) = 1$
 $E(W^2) = \frac{1}{(n-1)^2} E(T^2) = \frac{n+1}{n-1}$
 $T = \frac{(n-1)S^2}{\sigma^2} \sim \chi^2_{n-1}$
 $E(T) = (n-1), E(T^2) = (n-1)(n+1)$

So, the form of an affine equivariant estimator for sigma square this should satisfy delta of a x bar plus b a square S square is equal to a square delta of x bar S square. So, you choose b is equal to minus a X bar and a is equal to 1 by S so, then this will imply that delta of X bar S square is nothing but a constant times S square because this will become 0 this will become 1 so where k is a positive real. Let us look at the minimization of the risk of delta k that is equal to expectation of k S square minus sigma square by sigma square whole square let us use the notation.

SW is equal to say S square by sigma square that follow chi square n minus 1 actually it will depend upon what notation for S square I am using if I am using S square is equal to sigma X i minus X bar whole square by n minus 1 then we should have n minus 1 S square by sigma square follows chi square on n minus 1 degrees of freedom. So, we can use some modified notation here because I substituted here expectation of S square is equal to sigma square so, actually I am choosing the definition of S square as 1 by n minus 1 sigma X i minus X bar whole square.

So, let us use the notation (No audio from: 41:59 to 42:09) so, S square is equal to 1 by n minus 1 sigma X i minus X bar whole square and let us write this S square by sigma square as say W then this is reducing to expectation of k times W minus 1 whole square. Now, we can find out the minimization del R by del k that will give twice expectation k W minus 1 into W this will give k time is equal to expectation of W minus expectation of W square. Now,

let us look at these terms here expectation of W is equal to 1 because expectation of S square is equal to sigma square. What is expectation of W square? That will be equal to so if I calculate say T is equal to n minus 1 S square by sigma square that is chi square on n minus 1 degrees of freedom.

So, expectation of T is n minus 1 and expectation of T square is equal to n minus 1 square into n plus 1 n minus 1 into n plus 1 so, expectation of W is equal to because here W is equal to T by n minus 1. So, expectation of W square is 1 by n minus 1 square into expectation of T square so that gives us n plus 1 by n minus 1. So, this is equal to then expectation of W is equal to n minus 1 by n plus 1 so, n minus 1 by n plus 1 S square that is equal to 1 by n plus 1 sigma X i minus X bar whole square is the best affine equivariant estimator of sigma square.

(Refer Slide Time: 45:07)

$$\hat{\sigma}_{ML}^2 = \frac{1}{n} \sum (X_i - \bar{X})^2$$

$$\hat{\sigma}_{UM}^2 = \frac{1}{n-1} \sum (X_i - \bar{X})^2$$
 the best among these:
$$\hat{\sigma}_{BAE}^2 = \frac{1}{n+1} \sum (X_i - \bar{X})^2$$

$$L_1(\mu, \sigma, d) = \frac{(d - \mu - \eta\sigma)^2}{\sigma^2}$$

$$\theta = \mu + \eta\sigma \rightarrow \text{denotes a } p^{\text{th}} \text{ quantile}$$

$$\eta = \Phi^{-1}(p)$$

$$P(X \leq \theta) = P(X \leq \mu + \eta\sigma)$$

$$= P\left(\frac{X - \mu}{\sigma} \leq \eta\right)$$

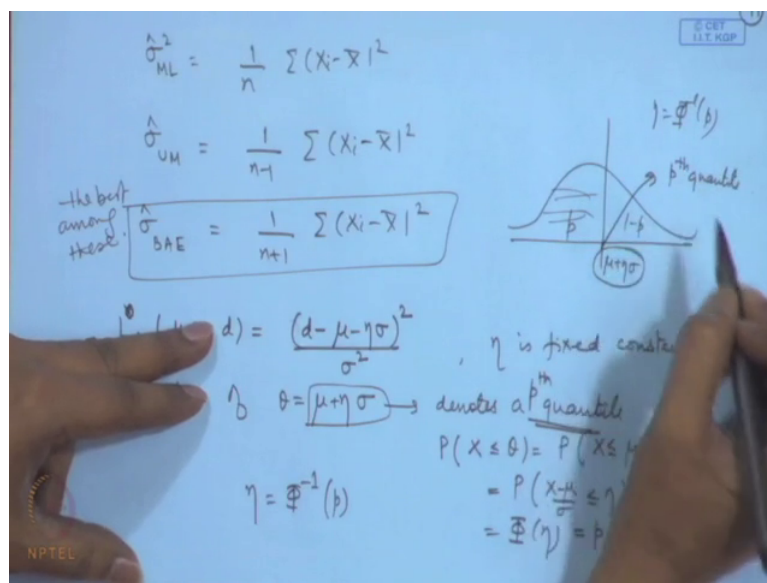

$$= \Phi(\eta) = p$$

So, let us take the whole thing in the perspective here for normal mu sigma square distribution we had sigma square M L as 1 by n sigma X i minus X bar whole square. We had the minimum variance unbiased estimator as 1 by n minus 1 sigma X i minus X bar whole square whereas, the best affine equivariant estimator is now 1 by n plus 1 sigma X i minus X bar whole square. Since all of these are only multiples of sigma X i minus X bar whole square this is the best among these two these three. So, you can see here that the principle of invariance allows us to improve upon the given estimators.

In the estimators which we have obtained using the method of maximum likelihood estimator method of moments or by the method of minimum variance unbiased estimation etcetera. Of course in this problem it can be further shown that even this best affine equivariant estimator can be further improved, but that is by another approach. So, we will not be doing that approach here now for this problem I want to give one more application here let us consider another loss function. Say L^* in place of L let us put $L = \frac{(d - \mu - \eta\sigma)^2}{\sigma^2}$.

Now, what is this problem this can be considered as estimation of $\theta = \mu + \eta\sigma$ where η is a fixed constant. See in the case of normal distribution $\mu + \eta\sigma$ denotes a quantile because here if I consider probability of X less than or equal to θ that is probability of X less than or equal to $\mu + \eta\sigma$ that is equal to probability of $X - \mu$ by σ less than or equal to η that is equal to $\Phi(\eta)$ where Φ is the standard normal cdf.

(Refer Slide Time: 47:47)

So if I put this is equal to p that is η is equal to $\Phi^{-1}(p)$ then this the p th quantile. Quantile of order p that means if I am considering the distribution here then this probability is p this probability is $1 - p$. So, this point is $\mu + \eta\sigma$ where η is given by $\Phi^{-1}(p)$ so, this the p th quantile. So, like mean median etcetera the quantiles also of interest to be estimated to denote or to find out various locations on the distribution let us consider the estimation of this here.

(Refer Slide Time: 48:30)

Consider the affine group.

$$\theta = \mu + \eta\sigma \rightarrow a\mu + b + \eta a\sigma = a(\mu + \eta\sigma) + b = a\theta + b.$$

So if $d \rightarrow ad + b$, then L_1 remains invariant.

Affine equivariant estimator must satisfy

$$d(a\bar{X} + b, a^2 S^2) = a d(\bar{X}, S^2) + b$$

$$b = -a\bar{X}, a = \frac{1}{S} \Rightarrow d(\bar{X}, S^2) = \bar{X} + kS$$

$$R(\mu, \sigma, d_k) = E\left(\frac{\bar{X} + kS - \mu - \eta\sigma}{\sigma}\right)^2$$

$$= E\left(\frac{\bar{X} - \mu}{\sigma}\right)^2 + E\left(\frac{kS - \eta\sigma}{\sigma}\right)^2 + 2E\left(\frac{\bar{X} - \mu}{\sigma}\right)E\left(\frac{kS - \eta\sigma}{\sigma}\right)$$

$$= \frac{1}{n} + E\left(\frac{kS - \eta\sigma}{\sigma}\right)^2$$

convex fn. of k

$E\left(\frac{\bar{X} - \mu}{\sigma}\right)E\left(\frac{kS - \eta\sigma}{\sigma}\right) = 0$

And so, consider the affine group now we have already seen here that μ goes to $a\mu$ plus b σ will go to $a\sigma$. So, what will happen to θ ? θ is equal to μ plus $\eta\sigma$ so, this will go to $a\mu$ plus b plus $\eta a\sigma$ that is equal to $a\mu$ plus $\eta a\sigma$ plus b that is equal to $a\theta$ plus b . Therefore, d must go to $a d$ plus b so, if that is happening then L_1 remains invariant. So, affine equivariant estimator if I consider affine equivariant estimator that must satisfy d of $a\bar{X}$ plus b a square S^2 is equal to $a d \bar{X} S^2$ plus b .

So, if you choose b is equal to minus $a\bar{X}$ and a is equal to $1/S$ then we get the form of $d \bar{X} S^2$ as \bar{X} plus because this will become a constant and we get minus $a\bar{X}$ and then we put $1/S$ so, S is multiplied by this constant plus this \bar{X} . That is the form which is the same which we obtained for the estimation of μ . Now, if you consider the risk function of this estimator that is expectation of \bar{X} plus kS minus μ minus $\eta\sigma$ by σ whole square then we can write it as expectation of \bar{X} minus μ by σ whole square plus expectation of kS minus $\eta\sigma$ by σ whole square plus two times expectation of \bar{X} minus μ by σ into kS minus $\eta\sigma$ by σ .

Now, here these terms are independent because in the sampling from normal distribution \bar{X} and S^2 are independent and this term becomes 0. So, the problem has reduced to minimization of this term expectation of kS minus $\eta\sigma$ by σ whole square. Now, this is a convex function of k so, the minimization will occur when we differentiate this with respect to k and put equal to 0.

(Refer Slide Time: 52:17)

The minimization with respect to k is achieved when $\frac{\partial R}{\partial k} = 0$

$$\frac{\partial R}{\partial k} = \frac{2}{\sigma^2} E(kS - \eta\sigma) S = 0$$

$$\Rightarrow k = \frac{\eta\sigma E(S)}{E(S^2)}$$

$$= \frac{\eta E(W^{1/2})}{E(W)}$$

$$= \frac{\eta \cdot \sqrt{2} \frac{\Gamma(n/2)}{\sqrt{n-1} \Gamma(n/2)}}{\frac{\sqrt{2} \frac{\Gamma(n/2)}{\sqrt{n-1} \Gamma(n/2)}}{\Gamma(n/2) \Gamma(n/2)}}$$

$W^{1/2} = \frac{T^{1/2}}{\sqrt{n-1}}$
 $E(W^{1/2}) = \frac{\sqrt{2} \Gamma(n/2)}{\sqrt{n-1} \Gamma(n/2)}$

$f_T(t) = \frac{1}{2^{n/2} \Gamma(n/2)} e^{-t/2} t^{n/2-1}, t > 0$
 $E(T^{1/2}) = \int \frac{1}{2^{n/2} \Gamma(n/2)} e^{-t/2} t^{n/2-1} dt$
 $= \frac{\sqrt{2} \Gamma(n/2)}{2^{n/2} \Gamma(n/2)}$

So, the minimization with respect to k is achieved when $\frac{\partial R}{\partial k}$ equal to 0 and $\frac{\partial R}{\partial k}$ is actually equal to twice expectation $k S$ minus $\eta \sigma$ into S equal to 0 that will give us k is equal to $\eta \sigma$ expectation of S divided by expectation of S square. Now, if we use the no terminology used in the derivation for estimation of sigma square we had defined T as n minus 1 S square by sigma square then this is following chi square distribution on n minus 1 degrees of freedom.

Now, expectation of S is coming in the terms of T to the power half so, let us calculate expectation of T to the power half. We have the density function of t as $\frac{1}{2^{n/2} \Gamma(n/2)} e^{-t/2} t^{n/2-1}$ where t is positive. So, expectation of T to the power half that will be $\int \frac{1}{2^{n/2} \Gamma(n/2)} e^{-t/2} t^{n/2-1} dt$ that is equal to $\frac{\sqrt{2} \Gamma(n/2)}{2^{n/2} \Gamma(n/2)}$ that is equal to $\frac{\sqrt{2} \Gamma(n/2)}{\Gamma(n/2)}$.

Now, S here we can consider S by sigma and S square by sigma square so, this is reducing to expectation of W divided by expectation of W square sorry expectation of W to the power half because here I get S by sigma so, this is W to the power half and expectation of W . Now, what is W to the power half that is equal to T to the power half by square root n minus 1 so, expectation of W to the power half is equal to $\frac{\sqrt{2} \Gamma(n/2)}{\Gamma(n/2)}$.

$n - 1$ by 2 . So, this term we substitute here $\eta \sqrt{2} \gamma \frac{n}{2}$ divided by square root $n - 1$ $\gamma \frac{n - 1}{2}$ and then expectation of W is equal to 1 .

(Refer Slide Time: 56:02)

The image shows a handwritten derivation on a whiteboard. On the left, it defines $W^{1/2} = \frac{\gamma^{1/2}}{\sqrt{n-1}}$ and $E(W^{1/2}) = \frac{\sqrt{2} \gamma^{1/2}}{\sqrt{n-1} \Gamma_{\frac{n-1}{2}}}$. In the center, it calculates $E(W)$ as $\frac{\eta \sqrt{2} \gamma^{1/2}}{\sqrt{n-1} \Gamma_{\frac{n-1}{2}}}$ and then $E(W^{1/2}) = \frac{\eta \sqrt{\frac{n-1}{2}} \cdot \frac{\gamma^{1/2}}{\Gamma_{\frac{n-1}{2}}}}{\sqrt{n-1} \Gamma_{\frac{n-1}{2}}} = k^*$. On the right, it shows $2^2 \frac{\gamma^{1/2}}{\Gamma_{\frac{n-1}{2}}}$ and $\frac{\gamma^{1/2}}{2 \Gamma_{\frac{n-1}{2}}}$, leading to $\frac{\sqrt{2} \gamma^{1/2}}{\Gamma_{\frac{n-1}{2}}}$. Below the equations, it states: " $\bar{X} + k^* S$ is BAE of $\theta \rightarrow$ quantile. It is better than MLE & UMVUE of θ ." An NPTEL logo is visible in the bottom left corner.

So, this is the term that we get of course, we can write it as $\eta \sqrt{2} \gamma \frac{n}{2}$ by $n - 1$ $\gamma \frac{n - 1}{2}$ so this is the best choice of k and we are getting \bar{X} plus let me call this as the this choice as say k^* S is the best affine equivariant estimator of θ that is the quantile. Once again you can see this is different from the maximum likelihood estimator so, it is better than MLE and UMVUE of θ . So, today we have discussed the concept of invariance in detail and we have seen that finding out the best invariant estimator under a certain group of transformations many times leads us to much better estimators than the conventional methods.

That we have discussed till now like the maximum likelihood estimation or the minimum variance unbiased estimation. Another point which is to be noted here we have not discussed it here till now is that there are procedures which can also lead to improvement over the equivariant estimators. But that is part of some advanced discussion if we find time we will be able to cover it somewhat later. So, I will also introduce some decision theory concepts such as the Bayes estimation and the mini max estimation in the next lectures.
