Lower Bounds of Variance - II

In the previous lecture, I explained the method of finding out a lower bound for the variance unbiased estimator for a given parametric version. As I mentioned it was derived independently by three statisticians Frechet-Rao and Cramer and therefore, we have named it as a Frechet-Rao-Cramer lower bound, that is FRC lower bound for the variance of an unbiased estimator.

We have seen that there are cases where we can find out an estimator, for which this lower bound is attained, there are also cases where it is not attained. We gave a condition, under which an unbiased estimator will attain this lower bound. The condition was in the terms that it should be linearly related with a function $S(X; \theta)$ with probability 1, this method as I had explained this method of lower bounds is very very useful from two points of view, one is that given any estimators we can compare its variance with the lower bound and therefore, we know that how far we are from the actual.

That means what could be the best possible way minimum variance and where are we; that means, where is our estimator standing in it is for relative position and second thing is that, if we are able to obtain an estimator, for which it is equal to the lower bound then certainly it is a minimum variance unbiased estimator that is among the unbiased estimator it will certainly be the best. So, from this point of view this method of lower bound is extremely useful. We have seen that FRC lower bound as I call it is dependent upon certain regularity conditions, that is when the density or the mass function under consideration satisfy certain conditions, then only this lower bound is valid. We also saw that what are the parametric functions for which this lower bound is attained.

(Refer Slide Time: 02:26)

So, let me give it in the form of a theorem. So, we have a random sample X_1, X_2, \dots, X_n and we know that the FRC lower bound, for the variance of an unbiased estimator of $g(\theta)$ is attained, then what are the parametric functions? Apart from $g(\theta)$ for which we have attained, then the answer is that they are actually the linear functions of $g(\theta)$ and then the class of parametric functions for whom the unbiased estimators attain this FRC lower bound, then this class is the class of linear functions of $g(\theta)$.

Like I said what is the unbiased estimator for which the lower bound will be attained that should be a linear function of $S(X, \theta)$ with probability 1. Now, what are the parametric functions for utility which will be attained and then they should simply be the linear functions of $g(\theta)$ that is the statement of this theorem.

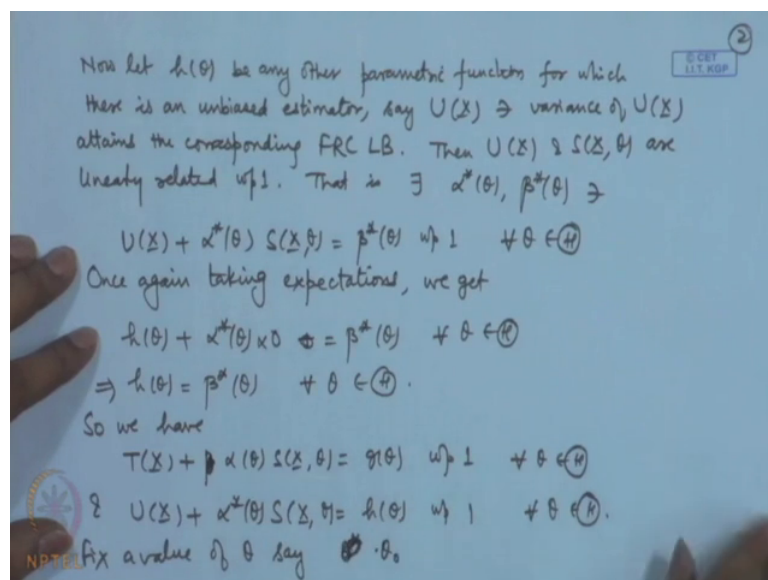

Let me prove this theorem here. So, let us consider $T(X)$, let $T(X)$ be an unbiased estimator of $g(\theta)$ and let variance of $T(X)$ equal the FRC lower bound, then certainly we know that $T(X)$ and $S(X, \theta)$, they are linearly related with probability 1, we will use this with probability one as an abbreviation here.

So; that means, there exists functions say $\alpha(\theta)$ and $\beta(\theta)$, such that say $T(X) + \alpha(\theta) S(X, \theta)$ is equal to say $\beta(\theta)$ with probability 1, this should be true for all θ . Now, in this relation let us take expectations on both the sides. So, expectation of $T(X)$

plus alpha theta expectation of S X theta is equal to beta theta for all theta since, this statement is true for all.

That means for random variable X here it is true with probability 1 therefore, it is possible to take the expectations basically, expectations means either we have taken summations or we have taken the integrals or a mixture of the two therefore, we will get expectation of these equal to beta theta. Now, T is unbiased estimator for g theta; that means g theta now, expectation of S X theta that is 0. Therefore this is simply giving you beta theta, because this is equal to 0. So, in this relationship beta theta has turned out to be g theta here.

(Refer Slide Time: 07:30)

Now, let h theta be any other parametric function, for which there exist an unbiased estimator, for which this lower bound is attained. So, for which there is an unbiased estimator say U X, such that variance of U X attains the corresponding FRC lower bound. We have seen that even if we change the parametric function, the lower bound is changed, but the conditions for attaining the lower bound remains the same therefore, So, there will exist that U X and S X theta are again linearly related with probability 1; that means, we can say that there exist say functions alpha star theta and beta star theta, such that U X plus alpha star theta into S X theta is equals to beta star theta with the probability 1 for all theta.

Once again since this statement is true with probability 1, we can take expectations. So, if we take expectations, we get expectations of U X will be equal to h theta plus alpha star theta

into expectation of $S(X, \theta)$ is 0 is equal to $\beta^* \theta$. So, we are getting $h(\theta)$ is equals to $\beta^* \theta$. So, if we look at this two equations now, $T(X) + \alpha \theta S(X, \theta) = g(\theta)$ and $U(X) + \alpha^* \theta S(X, \theta) = h(\theta)$ that will be equal to $g(\theta)$ and $U(X) + \alpha^* \theta S(X, \theta) = h(\theta)$.

So, we have $T(X) + \alpha \theta S(X, \theta) = g(\theta)$ with probability 1 for all θ and $U(X) + \alpha^* \theta S(X, \theta) = h(\theta)$ with probability 1, for all θ belonging to Θ . If this relationship is true for all θ , we can fix a value of θ say θ_0 or let me put θ_0 , because already stars are there.

(Refer Slide Time: 11:19)

$T(X) + \alpha(\theta) S(X, \theta) = g(\theta) \quad w.p. 1$
 $U(X) + \alpha^*(\theta) S(X, \theta) = h(\theta) \quad w.p. 1$
 Eliminate $S(X, \theta)$ from the two equations:
 $\alpha^*(\theta_0) T(X) - \alpha(\theta_0) U(X) = \alpha^*(\theta_0) g(\theta_0) - \alpha(\theta_0) h(\theta_0) \quad w.p. 1.$
 or $aT(X) + bU(X) = c$ where a, b, c are constants $w.p. 1.$
 Taking expectations, we get
 $ag(\theta_0) + bh(\theta_0) = c$
 So g & h are linearly related.

So, in that case we can write the relationship as $T(X) + \alpha \theta_0 S(X, \theta_0) = g(\theta_0)$ with the probability 1 and the $U(X) + \alpha^* \theta_0 S(X, \theta_0) = h(\theta_0)$ with probability 1; that means, what I have done is that these two relations I have written for a fixed value of θ that is θ_0 . Now, in both of these equations $S(X, \theta_0)$ is appearing. So, I can eliminate that. So, eliminate $S(X, \theta_0)$ from the two equations that, is in the first equation multiply by $\alpha^* \theta_0$, in the second equation multiply by $\alpha \theta_0$ and then subtract. So, we get $\alpha^* \theta_0 T(X) - \alpha \theta_0 U(X) = \alpha^* \theta_0 g(\theta_0) - \alpha \theta_0 h(\theta_0)$ with probability 1.

Now, once again you can take the expectation, because what is happening here is that this coefficient is a fixed number, this coefficient is a fixed number and right hand is also a fixed

number. So, we can say that a times $\sum X_i$ plus b times U equals to c , where a, b, c are constants and this statement is true with probability 1. So, we can again take expectations, if we take expectations we get a times $E(\sum X_i)$ plus b times $E(U)$ equals to c .

Now, you look at the significance of this I started with a function g , for which the FRC lower bound was attained. I assumed h to be another parametric function for which the lower bound is attained and now, we are getting that such g and h will be related using linear relationship here. So, g and h are linearly related therefore, all functions for which the FRC lower bound will be attained, they will be linear functions of g . Now, in yesterday's lecture I have given examples, in some examples the lower bound was attained.

(Refer Slide Time: 14:50)

Example: 1. Let $X_1, \dots, X_n \sim \mathcal{P}(\lambda), \lambda > 0$
 Let $\theta(\lambda) = \lambda^2$.
 FRCLB for variance of an unbiased estimator of $\theta(\lambda)$
 $= \{g'(\lambda)\}^2 \cdot \{ \text{FRCLB for } \lambda \}$
 $= 4\lambda^2 \cdot \frac{\lambda}{n} = \frac{4\lambda^3}{n}$.
 Let $Y = \sum X_i \sim \mathcal{P}(n\lambda)$.
 $U = \frac{1}{n^2} Y(Y-1)$. Then $E(U) = \frac{1}{n^2} (EY^2 - EY)$
 $= \frac{1}{n^2} (n\lambda + n^2\lambda^2 - n\lambda) = \lambda^2$.
 $\text{Var}(U) = \frac{4\lambda^3}{n} + \frac{2\lambda^2}{n^2} > \frac{4\lambda^3}{n}$.

Let us take one such example, say Poisson distribution. So, we had X_1, X_2, \dots, X_n , following Poisson λ where λ is positive, we have seen that \bar{X} was unbiased for λ and variance of \bar{X} was λ/n , which was also the FRC lower bound for unbiased estimator of λ . So, if I consider say λ^2 , let $g(\lambda) = \lambda^2$. In that case what we will get? The FRC lower bound for variance of an unbiased estimator of $g(\lambda)$ now, that will be equal to $\{g'(\lambda)\}^2$ into the FRCLB for λ . So, this will become $4\lambda^2$ times λ/n that is $4\lambda^3/n$. So, it is equal to $4\lambda^3/n$.

So, now let us consider say y is equal to $\sum X_i$ of course, this will follow Poisson $n\lambda$ and you can look at y into $y - 1$ by n square let me call it to be say U , then expectation of U it is equal to 1 by n square expectation of y square minus expectation of y , that is equal to now, this will become equal to now, $n\lambda$ plus n square λ square minus $n\lambda$ expectation of y square is $n\lambda$ plus n square λ square, because we can see that Poisson distribution with parameter λ . The second moment is λ square plus λ and expectation y is equal to $n\lambda$. So, this divided by n square. So, that is equal to λ square.

But if we consider say variance of U that will be equal to this can be calculated easily, that will turn out to be, because this will involve expectation of U square minus, expectation of U whole square. Now, expectation of U is λ square and expectation of U whole square will be involve expectation of y to the power 4, expectation of y Q and expectation of y square which is available. All the expression there further Poisson distribution after simplification you get it as, 4λ cube by n plus twice λ square by n square.

Now, you can easily see that this is bigger than 4λ cube by n , it is understood that this statement should be true, because λ square is not linear function of λ here. We have already shown that for λ the variance of the unbiased estimator are tensed the lower bound. Therefore, all other function for which we will attain for the form $a\lambda + b$ and this is λ square. So, suddenly this cannot be attained, later on we will show that actually this is minimum variance and y estimator using another method.

(Refer Slide Time: 18:34)

The image shows a handwritten derivation on a blue background. At the top right, there is a small logo with the number 5 and the text '© IIT KGP'. The text 'Exponential Family:' is underlined. Below it, the general form of the exponential family is given as $f(x, \theta) = c(\theta)h(x) e^{Q(\theta)T(x)}$. An example is provided: 'Examples: 1. $X \sim \text{Bin}(n, p)$, n is known'. The binomial probability mass function is written as $f(x, p) = \binom{n}{x} p^x (1-p)^{n-x}$. This is then rewritten as $\binom{n}{x} (1-p)^n \left(\frac{p}{1-p}\right)^x$, and finally as $(1-p)^n \binom{n}{x} e^{x \log\left(\frac{p}{1-p}\right)}$. The conclusion is written as 'So binomial distⁿ (with n known) is in exponential family.' The NPTEL logo is visible in the bottom left corner.

Exponential Family:
 $f(x, \theta) = c(\theta)h(x) e^{Q(\theta)T(x)}$

Examples: 1. $X \sim \text{Bin}(n, p)$, n is known

$$f(x, p) = \binom{n}{x} p^x (1-p)^{n-x}$$
$$= \binom{n}{x} (1-p)^n \left(\frac{p}{1-p}\right)^x$$
$$= (1-p)^n \binom{n}{x} e^{x \log\left(\frac{p}{1-p}\right)}$$

So binomial distⁿ (with n known) is in exponential family.

Let us consider general form of a distribution in the exponential family. So, let us consider a density in the exponential family. What is an exponential family? The densities of the form $c(\theta)h(x)e^{Q(\theta)T(x)}$. Now, if we have a distribution of these form, it is said to be distribution in the exponential family, we can see examples here say x follows binomial n, p here n is known, then the form of the distribution is $\binom{n}{x} p^x (1-p)^{n-x}$.

This we can write as $\binom{n}{x} (1-p)^n \left(\frac{p}{1-p}\right)^x$, this we write as $(1-p)^n \binom{n}{x} e^{x \log\left(\frac{p}{1-p}\right)}$. So, if you compare it with this pair here you have a function of the parameter that is $c(\theta)$ here θ is p , $h(x)$ is $\binom{n}{x}$, here e to the power $Q(\theta)T(x)$. So, here $Q(\theta)$ is a function here $\log\left(\frac{p}{1-p}\right)$ and x is the term $T(x)$. So, this is a distribution so, binomial distribution. Binomial distribution with n known is in exponential family, let us take some more popular examples in the statistics.

(Refer Slide Time: 21:06)

2. $X \sim \mathcal{P}(\lambda) \rightarrow$ Exponential family.

$$f(x, \lambda) = \frac{e^{-\lambda} \lambda^x}{x!} = e^{-\lambda} \cdot \frac{1}{x!} e^{x \log \lambda}.$$

Multiparameter Exponential family.

$$f(x, \underline{\theta}) = c(\underline{\theta}) h(x) e^{\sum_{i=1}^k \theta_i T_i(x)}, \quad \underline{\theta} \in \mathbb{R}^k$$

Ex $X \sim N(\mu, \sigma^2)$ both μ^2 σ^2 are unknown

$$f(x, \mu, \sigma^2) = \frac{1}{\sigma \sqrt{2\pi}} e^{-\frac{1}{2\sigma^2} (x-\mu)^2}$$

$$= \frac{e^{-\mu^2/(2\sigma^2)}}{\sigma} \cdot \frac{1}{\sqrt{2\pi}} e^{-x^2/(2\sigma^2) + \frac{\mu x}{\sigma^2}}$$

Two-parameter exponential family

Let us consider say x following Poisson lambda distribution. The form of the probability mass function is $f(x, \lambda)$, it is equal to $e^{-\lambda} \lambda^x / x!$, this we express as $e^{-\lambda}$ to the power minus lambda, lambda to the power x by x factorial, this we express as $e^{-\lambda}$ to the power minus lambda, $1/x!$ by x factorial, $e^{x \log \lambda}$ to the power $x \log \lambda$. Once again if we compare it with this particular form you can see here, $e^{-\lambda}$ to the power minus lambda is a function of lambda, $1/x!$ is a function of x . So, you can call it a $h(x)$.

X can be written as $T(x)$ and $Q(\theta)$ it is $\log \lambda$ here. So, you can easily see that this also a distribution in exponential family. We can actually also consider as a 1 parameter exponential family, we may also consider multi parameter exponential family, here parameter could be multi parameter here. So, here we write $c(\theta) h(x) e^{\sum_{i=1}^k \theta_i T_i(x)}$, i equals to 1 to k . So, θ could be say p dimensional and we may have this particular form here. So, this is actually called.

See if we have the same dimension here k , then this is called a k parameter exponential family. Let us consider say x following normal μ, σ^2 , here both μ and σ^2 are unknown, $f(x, \mu, \sigma^2)$ we can write as $1/(\sigma \sqrt{2\pi}) e^{-x^2/(2\sigma^2) + \mu x/\sigma^2}$, this we express in the following fraction.

If we expand this term you get a term μ^2 . So, you get minus μ^2 by $2\sigma^2$ and there is 1 by σ^2 here 1 by $\sqrt{2}$ by you have e to the power minus x^2 by $2\sigma^2$, plus μx by σ^2 now, this is a function of parameters here. So, this can be considered as a $c(\theta)$ function. This constant 1 by $\sqrt{2\pi}$ can be considered as a function of x alone and then you have you can write here $T_1(x) = x^2$ and $Q_1(\theta) = -1/2\sigma^2$. Similarly, here $T_2(x)$ can be taken to be x and $Q_2(\theta)$ can be considered to be μ/σ^2 . So, this is a distribution in two parameter exponential family.

Most of the standard distributions in a statistics that we use for example, gamma distribution with R known and λ are known that is a distribution and exponential family. If we consider a negative exponential distribution with a scale parameter that is also in the exponential family. So, there are various distributions which are actually in the exponential family. Now, exponential families have some important features and in particular with respect to the FRC lower bound.

(Refer Slide Time: 25:37)

$$f(x, \theta) = c(\theta) h(x) e^{Q(\theta)T(x)}$$

$$\log f(x, \theta) = \log c(\theta) + \log h(x) + Q(\theta)T(x)$$

$$\frac{\partial \log f(x, \theta)}{\partial \theta} = \frac{c'(\theta)}{c(\theta)} + T(x) Q'(\theta)$$

$$S(x, \theta) = \sum_{i=1}^n \frac{\partial \log f(x_i, \theta)}{\partial \theta} = n \frac{c'(\theta)}{c(\theta)} + Q'(\theta) \sum_{i=1}^n T(x_i)$$

Thus $W = \frac{1}{n} \sum_{i=1}^n T(x_i)$ is linearly related with $S(x, \theta)$ w.p. 1. Hence any linear function of W will be attaining the FRC LB for the variance of an unbiased estimator of $E(W)$.

We also determine $E(W)$ here.

So, let us consider in the context of the lower bound. So, if we are writing 1 parameter exponential family. Let us take log of this that is equal to log of $c(\theta)$, plus log of $h(x)$, plus $Q(\theta)T(x)$, if we consider the derivatives of this with respect to θ , we get $c'(\theta)/c(\theta)$, plus $T(x)$ into $Q'(\theta)$. Now, if you remember your $S(x, \theta)$ function it is nothing,

but $\sum_{i=1}^n \frac{\partial \log f(x_i; \theta)}{\partial \theta} = 0$. So, this becomes simply n times $\frac{\partial \log f(x; \theta)}{\partial \theta}$.

Now, you see here this is constant as far as variable is concerned. So, this is actually a linear function of $\sum_{i=1}^n x_i$. So, $S_x(\theta)$ is a linear function of $\sum_{i=1}^n x_i$. So, in the distributions which are in the exponential family, the variables or you can say the estimators which are linear functions of $\sum_{i=1}^n x_i$, the variances of them will be attaining the lower bound for the estimation of the expectations of these. So, what we are saying is, let us call it say w that is $\frac{1}{n} \sum_{i=1}^n x_i$. So, this is linearly related with $S_x(\theta)$ with probability 1.

Hence, any linear function of w will be attaining the FRC lower bound for the variance of expectations, for the variance of unbiased estimators of expectations w . We can also see that what will be this expectation in general, see in this particular case see we discussed some examples like a Poisson distribution. Now, in this Poisson distribution if you see $c(\theta)$ is $e^{-\lambda}$, its derivatives will also be equal to $e^{-\lambda}$.

So, you will get minus n here and Q is $\log \lambda$. So, Q' will become $\frac{1}{\lambda}$. So, you are getting minus n plus λ and this will become $\sum_{i=1}^n x_i$. So, when we say v , v is equal to \bar{x} and this w is equal to \bar{X} here. So, \bar{X} is attaining the FRC lower bound for expectation of \bar{X} that is λ . So, we have already proved this statement, I am just once again just demonstrating, that if the distribution is in the exponential family then all the linear functions of $\frac{1}{n} \sum_{i=1}^n x_i$ they will have variance equal to the FRC lower bound. So, this is a remarkable thing whenever we are having distribution in the exponential family there will be certain parameters for which the lower bound will certainly be attained. Now, let me now also obtain the expression for, what is the expectation of w . So, let us also we also determine expectation of w here.

(Refer Slide Time: 30:26)

$$\int f(x, \theta) d\mu(x) = 1$$

$$\Rightarrow \int c(\theta) h(x) e^{Q(\theta)T(x)} d\mu(x) = 1.$$
 Differentiating under the integral sign, we get

$$\int c'(\theta) h(x) e^{Q(\theta)T(x)} d\mu(x) + \int c(\theta) h(x) e^{Q(\theta)T(x)} Q'(\theta)T(x) d\mu(x) = 0$$

$$\Rightarrow \frac{c'(\theta)}{c(\theta)} + Q'(\theta) E_{\theta} T(X) = 0$$

$$\Rightarrow E_{\theta} T(X) = -\frac{c'(\theta)}{c(\theta) Q'(\theta)}$$

So, let us consider the integral or the summation of the density function or the mass function will be equal to 1. So, I general just integral meaning that it covers the discrete and continuous cases both. So, $c(\theta) h(x) e^{Q(\theta)T(x)}$ is equal to 1. Now, we may have certain assumptions here like differentiation to the integral sign will be assumed, because in the Rao-Cramer lower bound itself we make certain assumptions certain regularity assumptions. So, that assumptions should be true here also. So, if we assume that, then we can differentiate under the integral sign. So, we will get here there are two terms which involve θ . So, if we take the first one we get $c'(\theta) h(x) e^{Q(\theta)T(x)} d\mu(x)$.

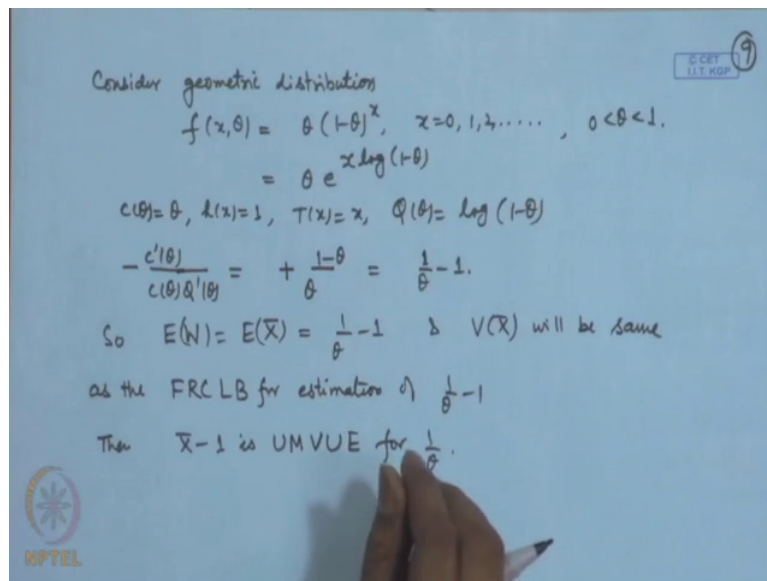

And if you differentiate the second term, you will get $c(\theta) h(x) e^{Q(\theta)T(x)} E_{\theta} T(X) d\mu(x)$ and of course $Q'(\theta)$ will also come this is equal to 0 the right hand side is 1. So, the derivative is going to be 0. Now, this term we can write as divided by $c(\theta)$ multiplied by $c(\theta)$, then that will be integral of the density once again. So, that will become equal to 0, if you look at the second term this density is as such then you are forgetting this term as additional term. So, $Q'(\theta) E_{\theta} T(X)$ is equal to 0.

That means what we are saying, expectation of θ expectation of $T(x)$ is actually equal to minus $c'(\theta) / (c(\theta) Q'(\theta))$ consider for example, the case of Poisson distribution, in the case of Poisson distribution c was $e^{-\lambda}$. So, c

prime theta by c theta will become equal to minus 1 that is minus minus becomes plus Q prime theta that will become 1 by lambda.

So, if you put it in the down later you will get lambda here, then in the case of Poisson distribution will become lambda sigma of T x i by n was X bar. So, the statement is that, that x bar will attain FRC lower bound for the estimation of lambda. So, that statement we verify directly now, if we are having that estimation that exponential family this will be always true.

(Refer Slide Time: 33:52)

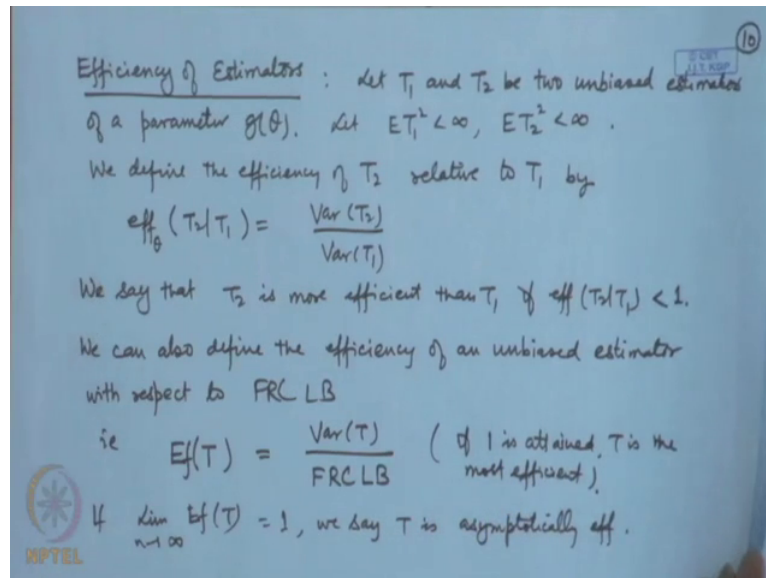

Let me take one more application here, consider say geometric distribution. Yesterday we have seen, here the form of the distribution taken theta into 1 minus theta to the power x for x is equal to 0, 1, 2 and so on. So, we can write this is equal to theta e to the power x, log 1 minus theta. So, here c theta is equal to theta, if you compare with the distribution here with the exponential family h X is 1, T x equals to x and Q theta is equal to log of 1 minus theta. So, naturally minus c prime theta by c theta Q prime theta, that is going to be equal to minus 1 c theta is theta Q prime theta will become equal to minus 1 by 1 minus theta. So, it is equal to 1 by theta minus 1; that means, and here x T x equals to x. So, w is equal to X bar.

So, expectation of w, that is equal to expectation of X bar is equal to 1 by theta minus 1 and variance of X bar will be attaining the Rao-Cramer lower bound will be same as the FRC lower bound for estimation of 1 by theta minus 1. So, now if you can see there a linear function of it is 1 by theta also we can consider. So, we can say that X bar minus 1 is

minimum variance unbiased estimator for θ . So, this statement is also true now, we have discussed the concept of minimum variance; that means, among unbiased estimators, the estimator which has the minimum variance is considered to be the best. In general we can always compare unbiased estimators by comparing the variances; that means, the one which has the smaller variance is considered to be more stable or better.

(Refer Slide Time: 36:43)

So, there is a classical concept of efficiency of estimators based on this, let me discuss that here efficiency of estimators. So, let T_1 and T_2 be two unbiased estimators of a parameter say $g(\theta)$ and let us assume that, they have the finite second moment this condition is required, because the variance must exist. So, we define the efficiency of T_2 relative to T_1 by. So, we use a notation of $Eff(T_2|T_1)$, it is equal to variance of T_2 divided by variance of T_1 . Naturally, if the variances are equal then the efficiency will be equal to 1.

If the efficiency is less than 1; that means, the variance of T_2 is less than variance of T_1 ; that means, T_2 is more efficient than T_1 conversely, if the efficiency is more than 1 variance of T_2 will become bigger than variance of T_1 ; that means, T_1 is better than T_2 . So, we say that we say that T_2 is more efficient than T_1 , if efficiency function is less than 1.

Now, this is regarding any two estimators now in general given any estimator we can consider its efficiency with respect to the Rao-Cramer lower bound. So, for example, we can consider estimators which attain the FRC lower bound if that is. So, then that is a benchmark

or you can say the best thing. So, anything which is bigger than that it is efficiency will be considered with respect to that.

That means its efficiency will be bigger than one. So, we can also define the efficiency of an unbiased estimator with respect to FRC lower bound, that is we may say let me give another notation we may call it E notation. So, efficiency of an unbiased estimator E f efficiency of an estimator T, we define as variance of T divided by FRC lower bound for the variance of unbiased estimator for that parameter. Suddenly, we know that sometimes this may be attained and sometimes it may not be attained.

So, these definitions are not full proof another thing is that in certain cases we may not consider unbiased estimators, because if we consider only mean square as a criteria it may turn out that the means square error is less than the variance by combining certain terms. We can also consider that although this may not be attain asymptotically it attain. So, we can give a definition that, if limit of this is equal to 1 then we say that T is asymptotically efficient. So, here if 1 is attained T is the most efficient.

(Refer Slide Time: 41:22)

Examples. 1, $X \sim \mathcal{P}(\lambda)$, our parameter of interest is

$$P(X=0) = e^{-\lambda} = g(\lambda)$$

$$\text{FRLB for } e^{-\lambda} = \left\{ \frac{g'(\lambda)}{g(\lambda)} \right\}^2 \cdot \{ \text{FRLB for } \lambda \}$$

$$= \lambda e^{-2\lambda}$$

Consider an estimator $\beta(X) = 1$ if $X=0$
 $= 0$ if $X=1, 2, \dots$

$$E\beta(X) = 1 \cdot P(X=0) + 0 \cdot \sum_{i=1}^{\infty} P(X=i) = e^{-\lambda}$$

So $\beta(X)$ is unbiased for $e^{-\lambda}$.

$$E\beta^2(X) = e^{-\lambda}, \quad \text{Var}(\beta(X)) = e^{-\lambda} - e^{-2\lambda}$$

$$e^{-\lambda} - e^{-2\lambda} > \lambda e^{-2\lambda} \Leftrightarrow e^{\lambda} > 1 + \lambda, \quad \lambda > 0$$

which is always true.

Let us look at some examples here, let us go back to the Poisson example and for convenience. Let me restrict attention to 1 observation, suppose X follow Poisson lambda and here our parameter of interest is say probability X is equal to 0 that is e or minus lambda of course, we may ask the question that, why we are considering this function. Now, usually a

Poisson distribution is the distribution of the number of arrivals number of occurrences during a given time interval or during a given area or during a given space etcetera. Now, what happens for example, considering a Q, service Q then how many people are arriving that will denote the number X, then certainly it is of interest to know that if X is equal to 0; that means, there is a slab period.

Because there is in a service Q it may happen that we may have to employ a service personal that is the persons who will be giving the service for example, it is a railway ticket counter, it is a ticket counter at a cinema hall or it is a service counter at a popular say café. So, therefore, persons are required there are personal are required, in then when there are no person; that means, when X equals to 0 we need not deploy the people or we may deploy less number of people.

So, certainly in such cases it is of interest to know or estimate the probability of 0 occurrences. So, this gives us this parametric function, $e^{-\lambda}$ certainly, it is a non-linear function of λ therefore, the variance of unbiased estimator of $e^{-\lambda}$ can never attain the lower bound. Let us look at this what will be the lower bound FRC lower bound for $e^{-\lambda}$ that is equal to $\frac{1}{n\lambda^2}$ square into the FRC for λ , for λ it is λ by n and if n equal to 1 then it is simply λ . The derivative of $e^{-\lambda}$ is $-e^{-\lambda}$ with a minus sign when we square it with $e^{-2\lambda}$.

So, this is λ this is a lower bound. So, now let us consider an estimator say β_X is equal to 1, if X equals to 0 it is equal to 0, if X equal to 1 2 and. So, on then if you look at expectation of β_X that is equal to 1 into probability X equal to 0 plus 0 into probability is equal to X say I is equal to 1 into infinity. So, this becomes 0. So, this is $e^{-\lambda}$. So, β_X is unbiased for $e^{-\lambda}$; however, if you look at expectation β_X^2 . Now, this will again be same and therefore, variance of β_X that is also $e^{-\lambda} - e^{-2\lambda}$. Now, if you compare this with the lower bound, $e^{-\lambda} - e^{-2\lambda}$ greater than $\lambda e^{-2\lambda}$. Because this is equal into $e^{-\lambda}$ greater than $1 + \lambda$ for λ positive which is always true. So, you can see that this lower bound is not attained.

(Refer Slide Time: 45:53)

We can actually show that β is the only unbiased estimator.

Let $\alpha(x)$ be an unbiased estimator of $e^{-\lambda}$.

$$\Rightarrow E \alpha(X) = e^{-\lambda}$$

$$\Rightarrow \sum_{x=0}^{\infty} \alpha(x) \frac{e^{-\lambda} \lambda^x}{x!} = e^{-\lambda} \quad \forall \lambda > 0$$

$$\Rightarrow \alpha(0) + \alpha(1)\lambda + \alpha(2)\frac{\lambda^2}{2!} + \dots = 1 \quad \forall \lambda > 0$$

$$\Leftrightarrow \alpha(0) = 1, \alpha(1) = \alpha(2) = \dots = 0$$

$$\Rightarrow \alpha(x) = \beta(x) \quad \forall x.$$

So $\beta(x)$ is UMVUE.

However, we can use another argument to actually prove that beta X is we can actually show, that beta is the only unbiased estimator. We can proceed by the basic principles let us consider say alpha X, let alpha x be a unbiased estimator of e to the power minus lambda, then we should have expectation of alpha x equal to e to the power minus lambda. Now, let us write down this relation alpha x, e to the power lambda, and lambda to the power x by x factorial is equal to e to the power minus lambda for all lambda. Now, this e to the power lambda you can remove from both the sides, because this is positive term. So, this reducing to then alpha 0 plus alpha 1 into lambda, plus alpha 2 into lambda square by 2 factorial and.

So, on is equal to 1. So, left hand side is a power series in lambda, hand right hand side is simply constant. So, this is true, if an only the coefficients match; that means, alpha 0 must be 1 and alpha 1 alpha 2 and so on. All of them must be 0 which is the same as the function beta, because beta 1 beta 0 was 1 and beta 1, beta 2 and. So, on when all of them were 0. So, this alpha function and beta functions are the same. So, beta must be UMVUE. So, although here the lower bound is not attained, but actually beta will be the most efficient estimator here.

(Refer Slide Time: 48:08)

Example: Let X_1, \dots, X_n be i.i.d. r.v. with mean μ and variance $\sigma^2 (< \infty)$.

$T_1 = \bar{X}, \quad T_2 = \frac{2}{n(n+1)} \sum_{i=1}^n i X_i$

$E(T_1) = \mu, \quad \text{Var}(T_1) = \frac{\sigma^2}{n}$. So T_1 is unbiased & consistent for μ .

$E(T_2) = \frac{2}{n(n+1)} \sum_{i=1}^n i \mu = \frac{2}{n(n+1)} \cdot \frac{n(n+1)}{2} \cdot \mu = \mu$.

$\text{Var}(T_2) = \frac{4}{n^2(n+1)^2} \sum_{i=1}^n i^2 \sigma^2 = \frac{4}{n^2(n+1)^2} \cdot \frac{n(n+1)(2n+1)}{6} \sigma^2$

$= \frac{2}{3} \cdot \frac{2n+1}{n(n+1)} \sigma^2 \rightarrow 0$ as $n \rightarrow \infty$.

So T_2 is also unbiased and consistent for σ^2 .

Let me give an example of comparing two unbiased estimators with respect to their variances. The estimators may both may be unbiased, both may be consistent etcetera. So, let us take another example, I am not taking any distributional form let us consider say X_1, X_2, \dots, X_n , n independent and identically distributed random variables with say mean μ and variance σ^2 ; obviously, we are assuming that variance is finite here now, you consider two unbiased estimators.

Let me take T_1 equal to \bar{X} and T_2 is equal to $\frac{2}{n(n+1)} \sum_{i=1}^n i X_i$; obviously, if you look at expectation of T_1 this we have seen that a sample mean is unbiased for the population mean, the variance of this is equal to σ^2/n . So, if estimator is unbiased its variance converges to 0, then we also know that it will be consistent. So, what we are seeing is that T_1 is unbiased and consistent for estimating μ .

Now, if you look at T_2 . So, that is equal to expectation of T_2 is $\frac{2}{n(n+1)} \sum_{i=1}^n i \mu$ is equal to $\frac{2}{n(n+1)} \cdot \frac{n(n+1)}{2} \cdot \mu = \mu$. So, T_2 is also unbiased let us look at variance of T_2 now, variance of T_2 if you take this is constant this will become square, $\frac{4}{n^2(n+1)^2} \sum_{i=1}^n i^2 \sigma^2$ equals to $\frac{2}{3} \cdot \frac{2n+1}{n(n+1)} \sigma^2$.

Variance of x_i is σ^2 since, we have assumed independence of the observations the correlation or covariance term will not come here, you will get this now σ^2 we have the formula. So, you get 4 by $n^2(n+1)^2$ into n plus 1 whole square n into n plus 1 into $2n$ plus 1 by $6\sigma^2$. So, after simplification you get it as 2 by 3 , $2n$ plus 1 divided by n into n plus 1 σ^2 . So, as n tends to infinity this goes to 0 .

(Refer Slide Time: 48:08)

$T_1 = \bar{X}, \quad T_2 = \frac{1}{n(n+1)} \sum_{i=1}^n i X_i$
 $E(T_1) = \mu, \quad \text{Var}(T_1) = \frac{\sigma^2}{n}$. So T_1 is unbiased & consistent for μ .
 $E(T_2) = \frac{2}{n(n+1)} \sum_{i=1}^n i \mu = \frac{2}{n(n+1)} \cdot \frac{n(n+1)}{2} \cdot \mu = \mu$.
 $\text{Var}(T_2) = \frac{4}{n^2(n+1)^2} \sum_{i=1}^n i^2 \sigma^2 = \frac{4}{n^2(n+1)^2} \cdot \frac{n(n+1)(2n+1)}{6} \sigma^2$
 $= \frac{2}{3} \cdot \frac{2n+1}{n(n+1)} \sigma^2 \rightarrow 0$ as $n \rightarrow \infty$.
 So T_2 is also unbiased and consistent for μ . $\frac{\text{Var}(T_2)}{\text{Var}(T_1)} = \frac{2}{3} \cdot \frac{2n+1}{n+1} > 1$ for $n > 1$.
 In general T_1 is more efficient than T_2 .

So, T_2 is also unbiased and consistent for σ^2 ; however, let us compare variances, what is variance of T_2 by variance of T_1 , variance of T_2 divided by variance of T_1 . So, σ^2 is coming here σ^2 is appearing here by n by n . So, that will cancel out.

So, you get the term as 2 by 3 , $2n$ plus 1 divided by n plus 1 ; obviously, this is always greater than 1 for n greater than 1 , if n equals to 1 of course, this will be equal to 1 and if n equal to 1 actually T_1 and T_2 are both equal to X_1 . So, that case is of not interest. So, in general T_1 is more efficient than T_2 . So, here you are seen we have two estimators both of which are unbiased as well as consistent for the sample mean, but for 1 of them can be preferred over the other, if we are applying the criteria of smaller variance.

(Refer Slide Time: 52:56)

Example: Let $X_1, \dots, X_n \sim N(0, \sigma^2)$
 Consider the estimation of σ .
 $f(x; \sigma) = \frac{1}{\sigma\sqrt{2\pi}} e^{-x^2/2\sigma^2}, \quad x \in \mathbb{R}, \sigma > 0.$
 $\log f(x; \sigma) = -\log \sigma - \frac{1}{2} \log 2\pi - \frac{x^2}{2\sigma^2}$
 $\frac{\partial \log f}{\partial \sigma} = -\frac{1}{\sigma} + \frac{x^2}{\sigma^3} = \frac{1}{\sigma^3} \left(\frac{x^2}{\sigma^2} - 1 \right)$
 $E \left(\frac{\partial \log f}{\partial \sigma} \right)^2 = \frac{1}{\sigma^6} E \left(\frac{x^2}{\sigma^2} - 1 \right)^2 = \frac{2}{\sigma^4}$
 $I_{\Sigma}(\sigma) = \frac{2n}{\sigma^4}, \quad \text{FRCLB for } \sigma = \frac{\sigma^2}{2n}.$

So, now let me also take another distribution say suppose, we consider a random sample from a normal distribution where mean is assumed to be 0 and variance is sigma square. We have already discussed this example in the context of estimation of sigma square when mu was some fixed value mu not now. Whenever, mu is some fixed value mu not you can always shift the observations. So, the mean can be made to be 0.

Now, suppose my interest is not to consider estimation of sigma square, but the estimation of sigma. So, consider the estimation of sigma say now, let us look at the lower bound. The density function is of the form when by sigma root 2 pi by e to the power minus x square by 2 sigma square where x is of course, any real value.

Log equal to minus log sigma minus 1 by 2, log 2 pi minus x square by 2 sigma square. So, derivative of this with respect to sigma that is minus 1 by sigma minus now, derivatives of this will become 0 and derivative of 1 by sigma square is minus 2 by sigma cube. So, it will become x square by sigma cube that is equal to 1 by sigma cube, we can write it as 1 by sigma x square by sigma square minus 1.

So, expectation of del log f by del sigma is equal to 1 by sigma square expectation of x square by sigma square minus 1 whole square. Now, if x follows normal 0 sigma square then x by sigma follows normal 0 1, x square by sigma square will follow chi square on 1 degree of freedom. So, therefore, this will have expectation 1 and therefore, expectation of the variable

minus it is mean square that is going to be the variance. Now, variance of a chi square is twice it is degrees of freedom. So, this term will become equal 2. So, this is simply equal to 2 by sigma square. So, if we consider the information that will be equal to 2 n by sigma square. So, the FRC lower bound for estimation of sigma that will be equal to sigma square by 2 n.

In the following class, I will consider two estimators for this see whether they any of them attain the lower bound and also compare them. So, that I will be doing in the following lecture.
